tissues were shown to be malignant by microscopic examination, and two in which the diagnosis of malignancy was clinical but unquestionable; 80 per cent. of the cases at least were therefore cancer. There were twelve patients in whom the diagnosis was "benign"; eight of which were microscopic, and four clinical diagnoses. Four of these patients have since suffered with recurrences which have been shown to be malignant, and in another case one portion of the tumor removed suggests a beginning malignancy, leaving only seven cases, or 15 per cent., continuously benign.

*Character of Operation.*—These forty-seven cases, in which suprapubic excision of the tumor was carried out, may be divided into three groups according to the extent of the operation performed.

*Group 1. Excision with pedicle and a portion of the vesical mucosa, twenty-three cases.* The operation here consisted generally in exposing the tumor by long median suprapubic incision and excellent retraction, every effort being made not to touch or disturb the tumor, which in some cases was first cauterized with hot-air cautery or with resorcin to kill the surface and prevent implantations, and then clamped across its pedicle close to the bladder, traction applied and one or more clamps placed across the pedicle higher up so as to include normal vesical mucous membrane; division of the pedicle below the deepest clamp by means of the Paquelin cautery, and hemostasis by means of clamps which were sometimes ligated, and sometimes left in place. Often the vesical wound, left after removal of the tumor, was thoroughly cauterized with the Paquelin cautery. Among these twenty-three cases there were only nine benign. Four of the benign afterward showed malignancy and one patient died of embolism soon after operation, thus leaving four benign cases, in one of which the patient suffered from an extensive benign recurrence; one patient has been lost sight of, and two have been cured now for four years each.

The results obtained in these nine benign cases are extremely bad, not nearly so good as is now obtained by fulguration, and they show in a striking way the inadequacy of the suprapubic excision even when great care is taken to avoid implantations, and to thoroughly remove the tumor after clamping its pedicle. One of the two cases, in which the patient is now well four years after operation, is extremely interesting in that it was one of the most unpromising cases of all, the bladder being almost completely filled with papillomas.

These were destroyed by a Paquelin cautery through a suprapubic incision, very little normal mucous membrane being left.

Microscopic examination of tumors showed all to be typically benign papillomas, except the largest specimen, in which an area suggesting early malignant changes was present. This case shows in a striking way the value of the cautery and probably also of resorcin in preventing vesical recurrences and prevesical implantations in cases of multiple papillomatosis.

*Malignant Cases.—There were fourteen cases* in Group 1 which were shown to be malignant, and in only two has the operation resulted in a cure.

Case 2.—A. S., aged 47, No. 21035, had a large papilloma about the size of an orange with its pedicle near the left ureteral orifice. It was clamped and excised with an area of mucous membrane, July 26, 1907. Patient writes under date of June 13, 1913, (six years later) that he is entirely well. Microscopic examination revealed an infiltrating papillary carcinoma.

Case 3.—The third case is quite remarkable. G. L. A., aged 69, admitted May 11, 1911, complaining of difficulty and frequency of urination and pain in the bladder, for several weeks had been treated at home by perineal exposures to the Roentgen ray with a view of curing the prostatic obstruction Examination showed an enlarged prostate, and a large red fissured rough tumor springing from a pedicle external to the right ureter. Suprapubic operation was performed May 19 1911. The tumor was found to be necrotic and friable, and when its pedicle was clamped the whole mass came away leaving a somewhat rough granular reddish base which was thoroughly cauterized with the Paquelin cautery. Examination of the tissues removed revealed a small hard growth in the midst of necrotic tissue, 2 by 3 cm. in size, and microscopic examination showed a papillary carcinoma. Cystoscopy four months later showed the bladder entirely healthy. Two years after operation the patient reports that he is entirely well.

This case is remarkable in showing an extensive necrosis of the tumor probably produced by Roentgen-ray treatments to which the patient had been subjected, and is another example of the efficiency of the cautery in the destruction of the base of these tumors.

The other twelve cases are a dismal recital of recurrence and death, more or less promptly, after the operation, with the exception of one case in which the bladder shows no recurrence, but the patient is suffering from a metastatic carcinoma of the right femur.

*Group 2. Four cases in which the excision of the tumor was accompanied by a more extensive removal of the adjacent vesical mucous membrane.* In all these cases the tumors were thought to be benign, but microscopic examination after removal showed three to be malignant, and in the fourth (thought to be benign clinically) the patient has since died of metastatic cancer. Two of these cases promptly recurred, one patient dying of a very extensive prevesical carcinoma, and the other carcinomatous metastases to the various bones.

One patient, J. H. L., is well now two and one-half years since the operation in which a globular tumor 2 inches in diameter was removed from the right lateral wall of the bladder.

In the fourth case, that of J. M., there was no local recurrence, but the patient died of cancer of the stomach and liver two and one-half years after operation. There is therefore only one of these four patients who has been apparently cured by this semiradical operation.

*Group 3. Twenty cases with more or less extensive resection of the entire thickness of the bladder wall adjacent to the tumor.* The extent of the resection varied from an area 1 or 2 inches in diameter to half the bladder in two cases, and almost all of the bladder in one case. In the latter (E. A. H.) the operation was performed with no hope of cure, but to relieve the patient of fearful pain of which he was suffering, which had not been relieved by double nephrostomy with diversion of the urine from the bladder. The abdomen was opened and all of the bladder excised with the exception of the trigonal portion. The patient experienced wonderful relief and lived six months, dying from metastases which were present before operation.

Among these twenty cases there were only three (L. S., H. M. D. and E.) which were benign although they appeared malignant with the cystoscope. In these three cases the tumor was excised with a wide area of healthy bladder wall through a suprapubic incision a year ago, and both patients report that they are well.

Seventeen cases were of cancer, and of these seven were found to be practically hopeless at operation, the cancer aving already extended beyond the confines of the bladder.

The other eleven may be considered to have been airly favorable cases.

(Cases 4, 5, 6, 7 and 8 have been omitted here. They ere all single tumors and completely resected with ladder wall; all apparently cured one to ten years.)

Case 9.—E. P. T., No. 594, aged 40, was admitted April 4, 904, with two small papillary tumors, one external to each reter, which were removed with the Paquelin cautery through suprapubic incision. One year later patient returned with ematuria. Cystoscope showed a small vesical tumor at the ower angle of the suprapubic incision, and two small pedunulated tumors on the left lateral wall. No recurrence where umors had been previously excised. All three tumors removed y clamp and cautery. Dec. 14, 1907: Patient says that or eighteen months he was entirely well, since which time there was hematuria. Cystoscopy revealed several recurrent vesical tumors. Suprapubic operation, excision with an area of bladder wall of several large tumors on the posterior wall of the bladder, a small tumor back of the right ureter and a small tumor back of the left ureter. Good result. Examination, June 18, 1911: No recurrence of bladder tumors. Patient now suffering with a small obstructing median prostatic bar (which was then removed with "punch" operation). Result good. June 4, 1913, a letter states that the patient is entirely well. Microscopic examination of tumors revealed cancer. Time since last operation, over five years. September, 1913, cystoscopic examination shows an infiltration in scar external to left ureter; a specimen removed by "*cystoscopic* rongeur" shows cancer, and laparotomy shows inoperable infiltration behind bladder. It is now nine years since first operation and six years since excision of last cancer.

Case 10.—H. J. S., No. 2038, aged 58, was admitted Dec. 1, 1908. Cystoscopy revealed tumor in the left half of the bladder. Suprapubic resection of wide area of left lateral wall encircling an ulcerative tumor 2 by 4 cm. in size. Bladder closed. Convalescence good. June 5, 1912, a letter states that the patient has remained entirely well, now five years since operation. Microscopic examination of tumor shows small round and spindle-cell sarcoma.

Case 11.—A. P. Y., No. 3286, aged 68, admitted September 17, 1912. Had been treated by fulguration. Cystoscopy revealed a fairly large sessile tumor on the anterior wall covered with grayish exudate. Suprapubic and intra-abdominal operation, resection of vertex of bladder with peritoneum, almost half of the bladder being removed. Closure, no leakage. Satisfactory convalescence. June 1, 1913, a letter states that the patient feels entirely well. Microscopic examination of tumor removed revealed cancer.

Case 12.—H. S. T., No. 3124, aged 57, was admitted March 12, 1912, with large flat irregular tumor on the right lateral wall of the bladder. Suprapubic resection of most of the right lateral wall of the bladder with a wide area surrounding the tumor. Ureter not transplanted. Tedious convalescence; very bad heart and extremely fat man. Examination Nov. 9, 1912, revealed the patient well with the exception of a contracted bladder and pyuria. January, 1913, chills and fever. Right kidney enlarged and tender. May 16, 1913, patient died of uremia and heart-disease. No necropsy obtained. No evidence of recurrence of tumor. Microscopic examination of specimen removed at operation showed carcinoma.

Case 13.—M. B. S., No. 25952, aged 72, was admitted May 16, 1910. Cystoscopy revealed an irregular tumor occupying the middle and left side of the trigon. Suprapubic excision of tumor with a good margin of mucous membrane and a portion of the muscle and the left ureter, the rest of which was transplanted. (Operation apparently not very radical.) Convalescence satisfactory. Patient well one year, but died of recurrence in twenty months. Microscopic examination of specimen showed an infiltrating carcinoma.

Case 14.—L. P. W., No. 26026, was admitted April 5, 1907. Cystoscopy revealed an irregular red tumor covering the left ureter. Suprapubic operation; tumor 3 by 2 by 2 cm. in size in the left corner of the trigon. Excised with a wide area of mucous membrane, including the end of the ureter, the rest of which was transplanted. Investigation showed an infiltration of the bladder wall externally to the line of excision. An additional area of bladder wall was then excised leaving an area about 5 cm. in diameter. Satisfactory convalescence. Jan. 14, 1908, and Dec. 23, 1909, letters stated that the patient was well. A letter, December, 1912, stated that the patient had had slight hematuria and cystoscopy showed recurrent tumor at the base of the bladder.

A review of the foregoing cases given in detail shows therefore only three recurrences, and at the time of operation examination showed in one an infiltration which required a second excision of bladder wall on account of the discovery of invasion of the bladder muscle. The case was therefore not a very hopeful one. Many of the other cases also required a very extensive resection. In one case half of the bladder was removed, and the results obtained are indeed extremely gratifying, and show, I believe, the importance of resection of the bladder wall whenever a suprapubic operation is carried out for vesical tumors. The results obtained by resection are, as indicated, far superior to those obtained by excision of the tumor with the pedicle and adjacent vesical mucosa when this operation seemed thoroughly complete as indicated in the twenty-three cases in Group 1.

### CLASS B. FULGURATION

These patients were treated by the high-frequency current, the Oudin current or the d'Arsonval current.

There are twelve benign cases in this class in which the treatment was given by means of the ureter catheterizing cystoscope, the electric spark being applied through an insulated copper or steel wire. The amount of current, the length of treatment and the number of applications vary in different cases. The results obtained have been so brilliant that it seems desirable to refer briefly to each case.

Case 15.—A., aged 30, who had undergone suprapubic excision of a small tumor three years before, had been bleeding profusely, and was in a desperate condition. *Hemoglobin* 16 per cent. Cystoscope showed a small bleeding tumor near the right ureteral orifice. Vein-to-vein transfusion from his wife was performed, hemoglobin increasing to 45 per cent. Tumor was then treated by high-frequency spark; *disappeared* with one application; bleeding ceased *immediately*. Examination six months later, entirely well. Bladder normal.

Case 16.—E. L. B., No. 3429, aged 47, was admitted Dec. 26, 1912, with a tumor 1½ inches in diameter with pedicle springing from the region of the right ureter. Treated five times with the ureter catheter cystoscope and high-frequency spark. Tumor then disappeared. Cystoscopy revealed a normal bladder. Letter four months later reported patient entirely well.

Case 17.—J. A. C., No. 3373, aged 59. Cystoscopy revealed seventeen small tumors in various parts of the bladder following a suprapubic operation eighteen months previously for removal of one tumor. Prostatic hypertrophy. Tumors destroyed by ten treatments with high-frequency spark. Cystoscopy then revealed a normal bladder and prostatectomy was carried out. Six months later, examination showed that the patient was entirely well.

Case 18.—J. T. C., No. 3821, aged 66, was admitted Sept. 12, 1912, with a small tumor in the right wall of the bladder. Prostatic hypertrophy. Was given three treatments with the high-frequency current, after which the tumor disappeared completely. Examination *June 5, 1913: Bladder* normal. Prostatic hypertrophy of moderate size. Residual urine, 80 c.c.

Case 19.—J. F., No. 3093, aged 45, was admitted Feb. 10, 1912, with hematuria of *two* years' duration. Cystosco showed six large papillomatous tumors in the left half of the bladder, varying from 1 to 1½ inches in diameter and covering almost all the left half of the bladder, including the ureter. The case seemed hopeless. At first little effect was seen; then following vigorous treatment with a long spark the tumors began to disappear rapidly, and in three months the bladder was perfectly normal. During the summer and fall of 1912 occasional treatments were given to very small remnants of tumor. Repeated cystoscopic examinations during the past six months show no recurrence. A really marvelous result.

Case 20.—McD., aged 45, was admitted, June, 1911, with small papillary tumor obscuring the left ureteral orifice which disappeared entirely under three vigorous high frequency treatments. Cystoscopy one year later showed no recurrence.

Case 21.—M., aged 35. Cystoscopy revealed two tumors, each about 1 inch in diameter, one in the region of the right ureter and the other slightly posterior to it on the lateral wall. Treated by high-frequency spark twice a week for six weeks. Examination then showed that both tumors had disappeared. Examination five months later shows no recurrence. Patient entirely well.

Case 22.—P., aged 30, was admitted, June, 1912, with hematuria. Cystoscopy revealed a papillary tumor about 1 inch in diameter in the region of the right ureter, and after four treatments the tumor entirely disappeared and examination six weeks later showed no recurrence. Patient still well.

Case 23.—G. S., aged 53, was admitted, Feb. 13, 1912, with hematuria of six months' duration. Cystoscopy revealed a large papillary tumor mass which covered the whole left lateral wall of the bladder. A piece of tumor removed with the rongeur showed a benign papilloma. High-frequency treatment given, first twice weekly and later once a week with slow disappearance of all the papillomas. Last examination, May 31, 1913, showed slight edema of the bladder, but no tumor. About twenty-five treatments in all were given.

Case 24.—W., aged 40, with a history of hematuria for several months, had a small raspberry-like tumor near the right ureteral orifice which was entirely destroyed by four high-frequency treatments at weekly intervals. Cystoscopy four months after last treatment showed the bladder entirely normal.

Case 25.—W., aged 50, who had had hematuria over a period of four years, was very weak from loss of blood. Cystoscopic examination showed the entire bladder covered with vesical tumors which in portions were villous and in others smooth. A piece of tumor excised with the cystoscopic rongeur showed a benign papilloma. Treatment was begun with the high-frequency spark; improvement at first was slight, but after two months, following vigorous treatments given biweekly, tumor disappeared within a month. Examination six months after last treatment showed a normal bladder, no scar being visible.

In the foregoing eleven cases the treatment has been followed by apparent complete cure of the disease. In the one case the treatment has just been begun, and the tumors are still present.

*Summary.*—A review of these cases shows that five were under 40 years of age; four between 41 and 50 years, and only three over 50 years of age. In four cases the tumor was small and disappeared quickly with three or four treatments of the high-frequency spark. In five cases there were one or two tumors 1 inch or more in diameter and in several instances they were not villous, but were red and granular in appearance. Specimens when obtained, however, showed that they were benign. From seven to twenty-five treatments were required to cause a complete disappearance of the tumors. In three cases the papillomatous disease was very extensive, the tumors being large and covering half of the bladder in two cases, and apparently the entire bladder in one case. The cure of these apparently hopeless cases by means of the high-frequency spark is indeed a brilliant result, and shows a great superiority of the method over suprapubic excision in benign cases.

*Malignant Cases.*—The high-frequency current was used with unsatisfactory result in almost all cases which proved malignant; the following is a good example:

Case 27.—B. V. L. C., aged 51, was admitted in the spring of 1912 with a papillary tumor in the right half of the bladder, external to the right ureteral orifice, not very villous in appearance, but no more malignant looking than some of the benign cases cured by the high-frequency spark. Ten applications some of which were very vigorous, resulted in the continued growth of the tumor, which was finally removed with a considerable portion of the right lateral wall of the bladder, and microscopic examination showed that it was definitely carcinomatous. Suprapubic resection of a portion of the bladder was then carried out, with success. The patient is now well, over a year later.

Another case also seemingly favorable resisted treatment by the high-frequency current. These two cases show very conclusively the importance of obtaining a good specimen for diagnosis early in the treatment, especially if the tumor fails to become smaller under high-frequency applications.

In four cases of extensive carcinomatous tumors of the bladder a partial destruction of the tumors, and improvement in frequency and difficulty of urination was obtained by the high-frequency current, but all of these patients have since died of metastases.

One case of carcinoma showed a wonderful disappearance under electrical applications.

In three cases splendid results have been obtained by the combined use of suprapubic excision, cauterization with the Paquelin cautery and high-frequency current.

(Reports of Cases 29, 30 and 31 are omitted for lack of space.)

It seems evident that it was possible to destroy malignant vesical tumors if the spark applied is strong enough, and with the bladder filled with air. This has caused me recently to apply fulguration through an open-air endoscopic cystoscope.

It is therefore evident that extremely thorough cauterization, whether done with the Paquelin cautery or by electricity, can successfully destroy vesical carcinoma, the principal need for care being to prevent implantations in the suprapubic wound and other parts of the bladder and to thoroughly destroy the base from which the tumors have been removed. Cystoscopy should be done frequently after the operation in order to detect and destroy recurrences early.

*Summary of Cancer Cases.*—Twelve cases have been treated by cauterization through the suprapubic wound. Three patients are apparently well, and one has a small recurrence. In one case the bladder was freed from carcinoma, but retrovesical metastases are now present. Five have died, and two are rapidly losing ground. That any beneficial results have been obtained in these apparently hopeless cases is indeed very satisfactory.

(On account of lack of space results in Classes C, D and E are omitted here.)

### GENERAL SUMMARY

A review of these 117 cases of vesical tumor, 83 per cent. of which were malignant, shows that excision, as usually carried out, is utterly inadequate and followed by prompt recurrence in both benign and malignant cases. The cautery is an extremely valuable agent in conjunction with suprapubic or intraperitoneal operations, and when it has been thoroughly applied even in apparently hopeless cases some brilliant cures have been obtained. Carcinoma of the bladder, except in very extensive cases, is best treated by suprapubic resection of the bladder, leaving a wide area of healthy wall around the tumor (the cautery used if possible), ureter transplanted if necessary, and the peritoneum excised when the tumor involves that portion of the bladder. Intraperitoneal operations are rarely necessary (except in tumors of the vertex and posterior wall), as an excellent view of the bladder can be obtained by an extensive median incision, wide separation of the recti muscles, upward displacement of the peritoneum, a long incision into the bladder and good retraction. The use of 50 per cent. resorcin, or alcohol, to kill any tumor particles which may have dropped into the bladder also seems desirable, but a better plan is to cauterize the tumor thoroughly before beginning the resection of the bladder. For benign tumors the treatment with the high-frequency spark seems thoroughly satisfactory, but should be vigorously applied, and for this purpose in extensive cases the fulgurating sound (Fig. 1) or the application of a strong spark through an open endoscope or cystoscope, the bladder being filled with air, may be very helpful. In apparently hopeless cases, destruction of the tumors and their bases and adjacent portions of the bladder wall by means of a Paquelin, hot-air or electric cauteries may occasionally give unexpected cures and brilliant results. Before applying treatment an adequate specimen should usually be obtained by means of the cystoscopic rongeur for microscopic diagnosis (Figs. 2 and 3). When one depends on examination of a few villi washed from the bladder or removed by small forceps a satisfactory diagnosis is often impossible and not infrequently erroneous. I have seen the diagnosis of benign papilloma made in malignant cases from such small bits of tissue, which often contain only the superficial villi of the tumor.

Fig. 1.—Gutta-percha sound carrying a large copper wire for vesical fulguration, without the use of the cystoscope.

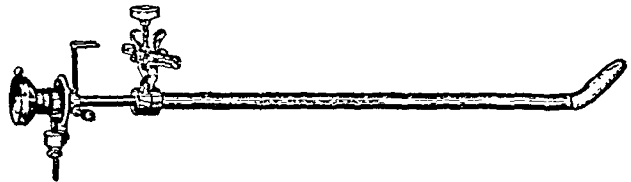

Fig. 2.—Cystoscopic rongeur closed, ready for introduction through the urethra.

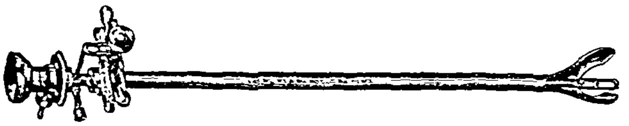

Fig. 3.—Cystoscopic rongeur open in position for grasping tumor in bladder. Later models are operated by scissors handles instead of the screw ratchet.

As in cancer elsewhere, success depends much on early diagnosis. One cannot urge too strongly the advisability of cystoscopic examination in all hematuria cases. Some cases of cancer of the bladder show few symptoms. One should not wait for blood in the urine before urging cystoscopy.

Only three years ago many authorities considered it almost impossible to cure benign papilloma of the bladder, and in many clinics abroad operations on cancer of the bladder were practically discontinued. The demonstration of the marvelous efficacy of high-frequency electrical applications is one of the most brilliant and valuable additions to surgery in recent years, and the proof that resection of the bladder wall offers a good chance of cure in cancer shows that the surgery of vesical tumors far from being a hopeless field, is indeed one of great promise.

330 North Charles Street.

## ABSTRACT OF DISCUSSION

**Dr. Hugh Cabot**, Boston: The whole question in regard to these bladder tumors turns on what we are to consider benign and what we are to consider malignant. We have all seen the pathologist undergo changes of heart, and I have come to believe that the opinion of the pathologist is quite as likely to be misleading as valuable, not because he cannot decide as to the nature of the specimen given him, but because these tumors undergo changes; especially is he likely to be wrong when dealing with portions of a tumor. Dr. Young has pointed out, and I think wisely, that in dealing with a tumor we must deal with large portions, that the little snips that we cut off with cystoscopic instruments are more likely to do harm than good; they are likely to be from the surface of the tumor, whereas it is the condition of the base that we should try to determine. We all know that the surface may long remain apparently benign, while the base is undergoing malignant change. It is not clear to me that we should regard these changes in the tumor as a degeneration. They seem to be progressive, and, in some cases at least, may be regarded as the natural history of these tumors. Again, we may get benign recurrences from malignant tumors and malignant recurrences from benign tumors. I have come to believe that our clinical view of these tumors is as likely to lead us to a correct surgical management as is the report of the pathologist, and that opinion can now be formed more readily by their behavior under the use of the high-frequency cauterization. It is of value not only in the destruction of the tumor, but also in the diagnosis of the type of growth. It appears from observations far more extensive than my own that the average malignant case behaves badly under high-frequency cauterization, although there are some rather prominent apparent exceptions, and that the benign cases show brilliant temporary results. How permanent the results are we are not in a position to decide.

At present there are two methods of election, the high-frequency cauterization and the radical, total resection of the portion of the bladder wall involved. I am much pleased to see Dr. Young advise the total resection of the bladder wall in the neighborhood of the tumor, because it has seemed that a lesser removal of the bladder wall is likely to be followed by recurrence. It seems to me that in all the apparently benign tumors the high-frequency current should be tried, and in the great majority of them it will prove efficient. There are benign tumors which must be dealt with radically owing to their size or the irritability of the bladder. The mere multiplicity of growths favors the high-frequency current as against radical operation.

In doing resection of the bladder it is important to include the peritoneal coat of the bladder if the tumor is located in the portion of the bladder covered by peritoneum.

**Dr. Granville MacGowan**, Los Angeles: The majority of cases of tumor of the bladder come to the surgeon only because of loss of blood. Hematuria is not of itself an uncomfortable thing, unless it is accompanied by pain or loss of strength. The majority of tumors of the bladder are at first ordinary papillomas—common warts—but for a reason that it is difficult to explain they have a tendency to become malignant growths, assuming a malignant growth to be one that has a tendency to destroy life, and not always paying strict attention to its appearance under the microscope.

I was interested in the report of a tumor disappearing after the use of a 20 per cent. solution of resorcin. I shall tell you what I think of that disappearance. Two years ago a man about 45 years old consulted me for incontinence of urine which had lasted about six months. He did not have tabes, he did not have an obviously enlarged prostate and he had no definite obstruction in the posterior urethra, but his bladder was filled up to above the navel and had been carrying an enormous amount of residual urine for a long time. Resorting to cystoscopy, I found that the whole superior bladder wall was covered with an enormous papilloma. It hung down into the mouth of the bladder and completely obstructed it. Under such circumstances anyone would think that he had found the reason for the obstruction. The man refused operation. He was put on the regular use of the catheter. About two months and a half ago, to satisfy one of his friends from whom I had removed the prostate, and who strongly believed that this man also had an enlarged prostate, he came again for examination. I performed cystoscopy and found no vestige of tumor on the superior bladder wall or elsewhere in the bladder. I think that the action of the resorcin in one case was exactly like the action of the remedy which I applied for the curing of this particular bladder tumor. I should regard the use of a 20 per cent. resorcin solution as of no value as a remedy for tumors of the bladder and a 50 per cent. solution as extremely dangerous.

In treating these tumors we must not be discouraged by the fact that we do not cure a large number of those that are cancerous. If we follow the plan so clearly set forth by Dr. Young, we shall perform a valuable service—we shall lengthen and make bearable the lives of many persons who would otherwise be condemned to a speedy death.

In 1900 I operated on a woman 68 years of age for multiple tumors of the bladder. I removed them by resection; some of them were simple papillomas; others were evidently cancerous. The operation was successful. Not until 1910 did she have any hematuria again. She was subjected to cystoscopy frequently during the ten years and no tumors were found in the bladder. In 1910 she appeared with two cancerous tumors on the left side of the bladder base. These were resected with fire, for I think that fire is the best agent to use. I prefer the electrocautery. The patient recovered and lived a year without pain and without hematuria, but died in 1913 from cancer of the bladder and of the pelvis. When we can accomplish so much in these cases, we should not entertain the pessimistic ideas which many surgeons and more pathologists have that nothing can be done for tumors of the bladder because they are necessarily fatal.

DR. A. C. STOKES, Omaha, Neb.: I have tried cauterization, high-frequency and resection. I have come to the conclusion that the first thing to try is resection, and after that, if you like, high-frequency or any other electrical application. Given a tumor of the bladder I resect the portion of the bladder in which it is contained with the electrocautery, if I can. If I cannot and the patient will not submit to it, I resort to the other methods mentioned.

I have been interested in the pathology of these tumors, and I find that parts of them represent a carcinoma and other parts represent a metastatic implantation of the mesoblast, so that some tumors of the bladder may, perhaps, be classified with the tumors of the kidney and the other genito-urinary organs, in that they are, in some cases at least, of mixed tumor type.

DR. LOUIS E. SCHMIDT, Chicago: Eight years ago Dr. Kolischer and I read a paper before the American Medical Association in regard to the operative treatment of bladder tumors, and at that time the opinion was exactly the same as that expressed by Dr. Young to-day. There is no question that the so-called benign tumor should not be clipped off, as it frequently is. A portion of the bladder wall should be resected. So far as positively malignant tumors are concerned, I do not think that there can be any argument that there must be complete resection widely distant from the base of the tumor. If there is a peritoneal coating about that point it should certainly be removed.

Eight years ago I reported a practically complete removal of the bladder, except the trigon, for sarcoma of the bladder. It was practically a Harrington operation. I think that it was the first intra-abdominal bladder operation that I had performed. The patient is still living. We need not have any fear as to the extent of resection, but should remove as much of the bladder as is absolutely necessary. I have operated on this man two or three times since for other conditions; I have had him under constant observation, and I venture to say that there is no one here who would examine this patient and not say that he had practically a new bladder formed. He holds his urine eight or ten hours and has no difficulty in the urinary act.

We should give more thought at present to these so-called inoperable tumors. About nine out of ten cancers of the bladder that I see are beyond operative interference. In cases in which curettment and partial cauterization with the thermocautery and treatment with those different remedies is resorted to, urosepsis has set in from which none of the patients have recovered. The patients have seldom left the hospital, and they have certainly not been improved. It is in this particular type of case that we should endeavor to be of some service. The use of the Roentgen ray in combination with the high-frequency current and other agents that might possibly be of some help will do a great deal to prolong life and relieve suffering.

DR. J. R. CAULK, St. Louis: I have seen twenty-six bladder tumors. Six of these were definitely malignant. Two of them were inoperable, so far as getting curative results was concerned. Two were resections and two were multiple tumors throughout the bladder which had evidently metastasized, the patients suffering great vesical disturbance; the bladder was opened partially resected and cauterized with closure. The other nineteen tumors were in eight patients, and these were treated with the high-frequency current. In every one of these tumors there was a rapid disappearance; some required eight, nine and ten cauterizations but the great majority of them, that is, the ones dating back a year, have recurred, but have been easily controlled.

In these eight patients with benign tumors, three of the growths have been associated with prostatic hypertrophy. Two of them were treated endovesically before prostatectomy. The other one had a large middle lobe, and I had to do a prostatectomy first, and then later cauterized the tumor. I should like to know what the consensus of opinion is about such a combination.

Is there a specific effect of this particular current on these bladder tumors? That question has been hotly debated, and there are pros and cons. I had one patient with two small bladder tumors, in which I cauterized one at one sitting. Three days later there was a definite ulceration in the region of the tumor that I had cauterized. The other tumor had rapidly disappeared without leaving any evidences of having been there. Whether or not it was caused by any specific affinity of this current, I do not know.

DR. D. N. EISENDRATH, Chicago: The question of cancers of the mucous membranes and the structures underneath, from the general surgical point of view, has resolved itself into checking extension by the lymphatic channels. One point which Dr. Young emphasized, namely, the removal by cautery of these malignant tumors I heartily endorse. He has recommended the removal by a wide margin and the use of the cautery through the entire thickness of the bladder. I think that the day is coming when we will adopt the same procedure in cancer of the bladder which we are to a great extent adopting in carcinoma of the tongue and the mucous membrane of the mouth; that is not the use of the knife, but of the cautery, in incising the tissues around the cancer, thus sealing up the lymphatics.

I believe that we have not followed cases of reimplantation of the ureter far enough to decide how many of these kidneys retain their function when we transplant the ureter into another portion of the bladder. I believe that a great many ureters lose their ureteral sphincter on account of the transplantation, and, as a result ascending infection is favored and frequently cicatricial closure of the vesical orifice of the transplanted ureter of the kind that results so often in transplantation of the bowel and other structures.

# THE TRANSVERSE INCISION AND ABDOMINAL FASCIA

## AS A METHOD OF APPROACH IN SUPRAPUBIC OPERATIONS ON THE BLADDER AND THE PROSTATE *

GRANVILLE MacGOWAN, M.D.
LOS ANGELES

In approaching the bladder from above, the usual incision to lay bare this organ penetrates the skin, its subjacent fascia, the intramuscular septum, or more often the sheath and fibers of one of the recti muscles, and the cellular structures overlying the bladder and anatomically directly in contact with it. The idea is primarily to cut so that we shall come directly on the septum between the recti muscles, opening the sheath of neither of them. This is often difficult and if the incision is made close to the pubic bones the pyramidalis muscles interposed between the recti muscles and within their sheaths, lead to confusion.

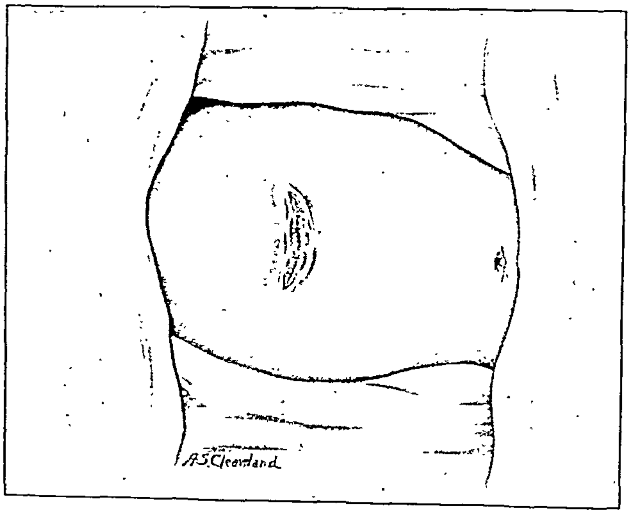

Fig. 1.—Transverse incision through the skin and superficial fascia.

If the person is stout, or if the abdominal muscles are very well developed, it is not easy to keep the lips of the wound retracted and obtain a good exposure. In manipulations within the bladder through such a wound, one may readily break down the cellular tissues in the space of Retzius. It is rough interference with this space and its infection through the working of septic material, during a prolonged operation, into its loose areolar tissue, and injury to the veins that course within it, which makes, in my opinion, for the greater mortality following suprapubic cystotomy than is observed in operations which open the bladder through the perineum.

If the bladder must be opened intraperitoneally for the removal of an extensive growth, room and light therefor may be obtained by the free extension upward of the longitudinal incision, but it is difficult to close an incision of this kind so perfectly as to do away with the probability of a postoperative hernia should the wound become an infected one. To obtain more room, one is obliged to make a transverse cut through the fascia and a portion of the muscles, or more often sever the recti or their insertions, close to the pubic bones. It is extremely difficult to bring the muscles again into their original relations and if they do become separated it makes a nasty weak spot in the abdominal wall. Several years ago I began to experiment with a transverse incision which extends through the skin, the superficial and deep fascia and a part, or the whole, of the sheath of the rectus muscle on each side. The first subjects I selected were persons with fat abdomens and large strong abdominal muscles. In such cases, using the longitudinal incision, it is extremly difficult to approach a deep-lying prostate or tumor of the bladder. At first I cut through the sheaths of the recti from their inner to their outer sides. Such an extensive incision is rarely necessary. Finding that this method of exposure of the bladder was so much easier and more satisfactory to me than the longitudinal one had been, for the past two years I have employed it exclusively. Every one knows that this incision has been used by many abdominal surgeons in various parts of the world for a long time for the approach to the peritoneal cavity, and I presume that many other people have used this incision for approach to the bladder, but I have never encountered any description of the operation for suprapubic cystotomy which I now propose to describe.

An incision from 3 to 6 cm. long is made transversely through the skin and superficial and deep fascias to the sheaths of the recti muscles, about 6 cm. above the spine of the pubis and slightly convex upward, to provide for better retraction of the skin. The deep fascia is pushed back both above and below the line of contemplated incision in the muscle sheaths for a distance of about 1 cm. so that a clear surface may be provided for the line of sutures when they are subsequently brought together. When divided its edges retract, exposing the body of the muscles. Then the intramuscular septum is to be slightly nicked below with scissors and rolled back with the sheaths, and the pyramidalis muscles appear. These consist of thin but well-marked muscular bodies which arise from the pubis and extend diagonally from each side to a point in the central tendon of the abdomen from 6 to 8 cm. above the symphysis, filling in and strengthening what appears to be naturally a weak portion of the abdominal wall. The space between these two muscles is to be sought for and they are to be separated or pressed apart by the handle of the knife. Sometimes it is necessary to split their fibers, especially at the apex, before they and their corresponding recti muscles can be pulled apart. Just as soon as this is accomplished the recti can be retracted easily. If the bladder has been previously

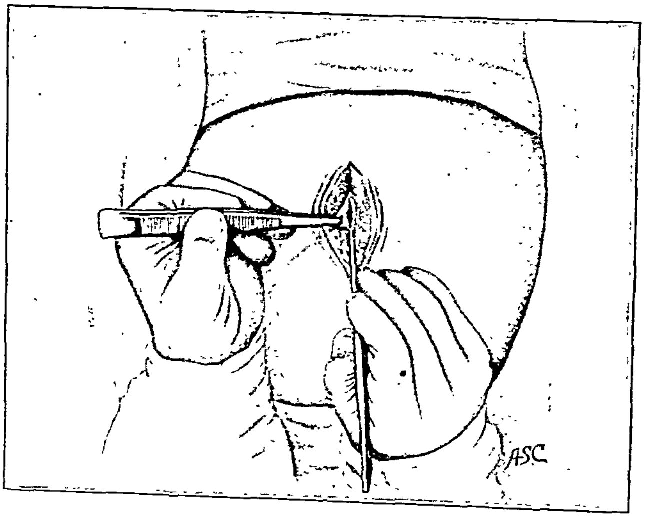

Fig. 2.—Opening of the muscular sheath.

---

* Read in the Section on Genito-Urinary Diseases of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

filled with water or air, it appears in the wound covered only by a thin layer of areolar fatty tissue. It is not necessary to push and dig around to find this organ. It should be grasped in the lower angle by an Allison forceps and pulled up and two sutures of silk, linen or celluloid thread passed through the muscular coat, one on each side, with a round-pointed, half-curved needle, to serve as traction sutures so that the bladder may not sink into the abdomen when the fluid which it contains is let out through the catheter before it is cut open or when it is punctured and the air is let out. The incision into the bladder may be made longitudinally or transversely. I am inclined to believe that the longitudinal incision is the better one. Then comes what, in my opinion, is the point of greatest importance in rendering a suprapubic cystotomy a nearly innocuous procedure, which should be accompanied by less than 1 per cent. of fatalities directly chargeable in any way to the operation itself. As soon as the bladder is opened as widely as desired, from two to four sutures should be inserted through all of its coats and the muscle or fascia of the muscle on each side, so that the space in front of the bladder and between it and the pubic bones shall not be disturbed by subsequent manipulations. If two of these stitches are placed in front, one on each side of the median line, and the bladder is held up by two other lateral stitches, it is kept during all of the course of the operation in such a relation to its surroundings that they do not become infected.

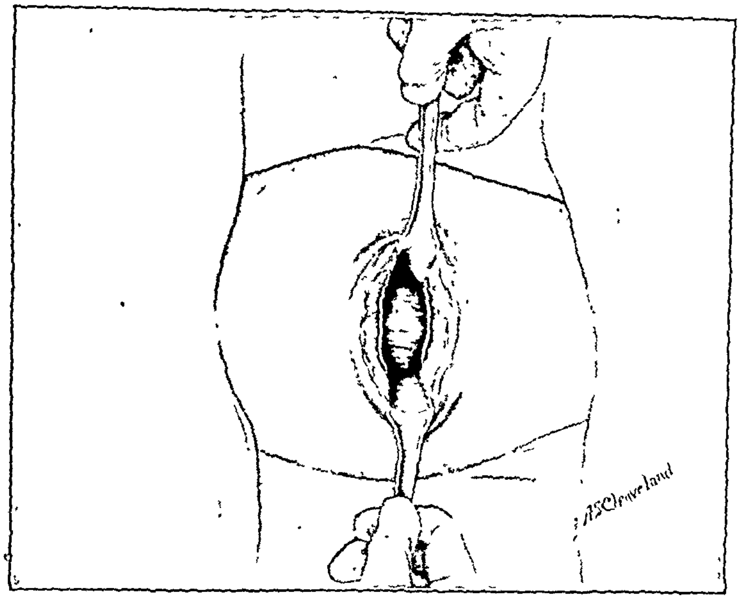

Fig. 3.—Exposure of recti muscles.

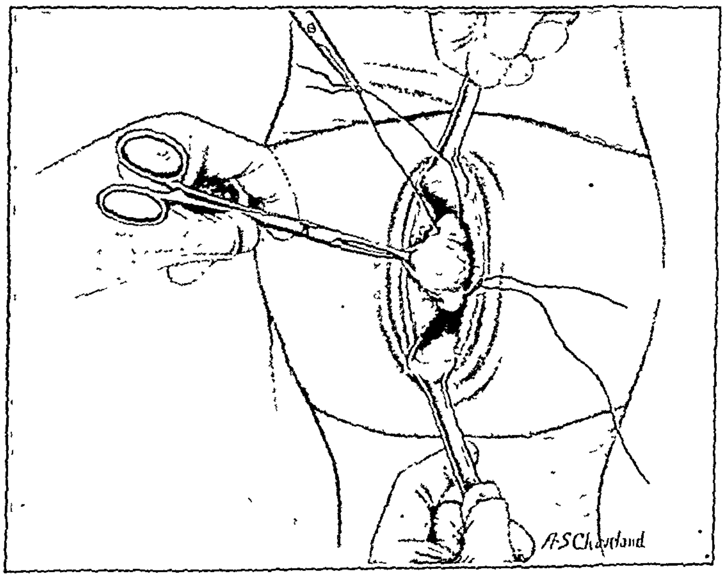

Fig. 4.—Retraction of the recti and pyramidalis muscles and the bladder drawn up by means of the Allison forceps, the traction sutures being introduced.

When the operation within the bladder is finished, if it is one that is accompanied by considerable hemorrhage which cannot be entirely stilled, or one which, as in the case of removal of the prostate, presents no immediate alarming hemorrhage but in which the loss of blood promises to be continuous and probably too great to permit of the closure of the bladder entirely, it should be closed partially around a drainage-tube sufficiently large so that it cannot become clogged with clotted blood. For this purpose I employ a piece of pure rubber tube 2.25 cm. wide and about 40 cm. long, provided with one or two lateral eyes close to its proximal extremity. This tube is slid along a gorget into the bladder before the removal of the supporting sutures. These sutures are then cut out one at a time and a purse-string suture of No. 2 catgut inserted through all of the muscular coats of the bladder about the tube. The traction sutures are kept in place until the purse-string has been inserted, so that an assistant can keep the bladder within sight. When the purse-string is in place, the last traction stitch is removed, because one has the bladder well under command with the purse-string suture, which is then tied and its competence tested by filling the bladder through a catheter in the urethra attached to an irrigator. If the purse-string has been properly placed it will be found that all of the water that enters the bladder passes out through the drainage-tube. The purse-string suture may be strengthened at each end by an interrupted suture. The upper surface of the bladder, which has been handled during the operation, and the surrounding narrow margin of cellular tissues are then mopped with tincture of iodin and the bladder allowed to fall back.

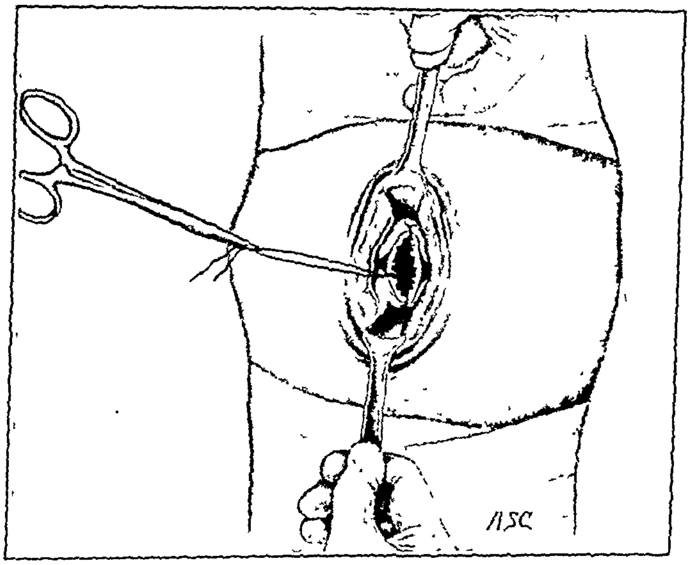

Fig. 5.—Supporting sutures introduced for the purpose of protection of cellular tissues surrounding the wound.

The large drainage-tube is placed just far enough within the bladder so that the eyes are entirely within the cavity, but the end of the tube does not touch the trigon. By this precaution tenesmus and strain and pain subsequent to the operation will be avoided. The bodies of the recti muscles at the upper angle are brought together by one or two catgut stitches. As I usually make use of spinal anesthesia or, for exploration or simple drainage or the removal of a stone, the infiltration anesthesia of a 4 per cent. solution of novocain, it is easy to tell how many sutures to place by requesting the patient to cough. The action of coughing throws the peritoneal fold up against the muscles so that one can see exactly where extra strength or protection is needed.

The edges of the sheath of the rectus muscle on each side must be brought together so that they overlap without tension. This stitch is a continuous one and is run with No. 2 iodized catgut, or with a No. 0 chromic catgut, the former preferred. The needle should be a small curved one, the smallest that will hold this size of catgut. The first stitch catches the extreme outer edge of the incision and is tied, with the ends left long. The second stitch is entered about 3 mm. from one edge of the sheath and the needle passed somewhat diagonally with the line of the incision outward to the edge of the deep fascia and then on the opposite side a corresponding stitch is taken; each should take up about 6 mm. of tissue. When this is tightened, it will be found that the edges of the incision come together easily and overlap, bringing the fatty tissues, which contain the blood-vessels, together to cover the tendon. This stitch is repeated until as much of the severed fascia is brought together as is possible without making too great tension in the center where the drainage-tube emerges. This stitch is much like a baseball stitch; instead of tying at the inner edge where it would make an extra knot, I continue it through the fatty tissue back to the point of beginning, where I tie it again. It does not take much time to place this suture and if it is carefully done there will not be any trouble about it holding securely until the tissues are united. The skin is best left open and will be closed when the bladder is healed. A small cigarette-drain is inserted at the upper and lower angles of the wound. I secure the drainage-tube to the skin with a Florentine suture, which must not pass through the tube, but through a small gauze trailer tied rather tightly about the tube just where it joins the skin, tying it in a bowknot so that it can be released, in case it is necessary to disturb the tube, without removing the suture from the skin.

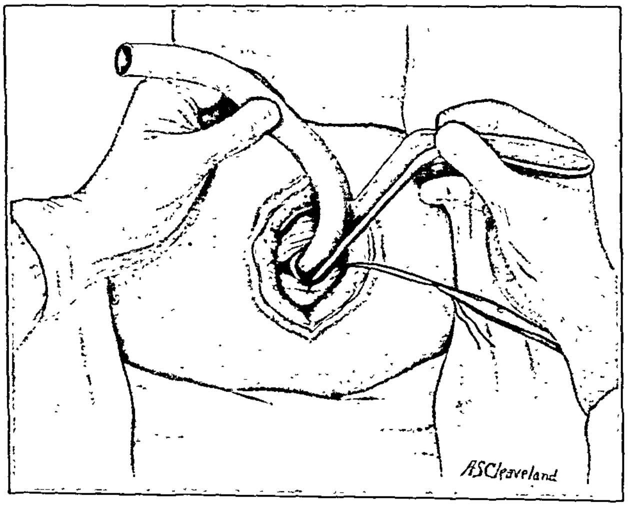

Fig. 6.—Placing of the suprapubic drainage-tube.

For many years I used a system of continuous irrigation in suprapubic cystotomies, in which the salt solution flowed into the bladder through a catheter inserted through the penis and passed out through a drainage-tube of moderate size; or entered through a small drainage-tube placed alongside of and secured to a larger one, both being sewed into the wound in the bladder; or I made use of a tube like that of Mr. Freyer. The latter I found inconveniently large, requiring an unnecessarily large incision, but effective in that it certainly keeps the bladder open and prevents the accumulation of clots; the others I found extremely destructive of my personal comfort, requiring attendance on patients at any hour of the day and night when the tubes would get obstructed and the nurse could not manage to get the flow started again, and the patients were often wet and uncomfortable. I tried also various mechanical appliances, some of which, like that of Bremmermann, are simple but not fool-proof.

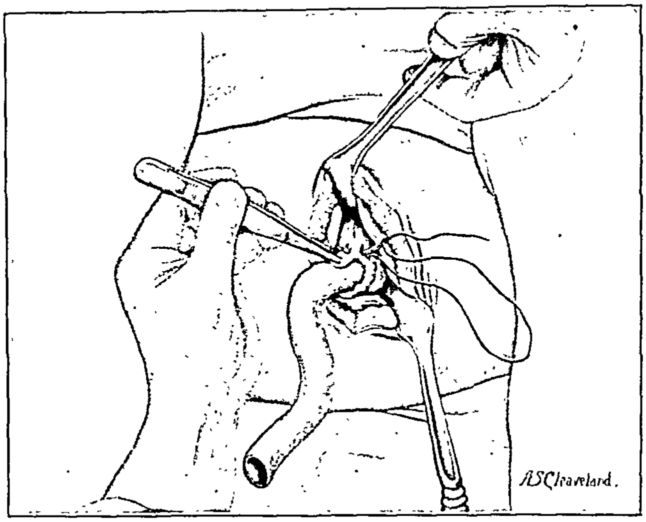

Fig. 7.—Introduction of the purse-string suture about the bladder wound.

I have devised a method of drainage which seems to me superior to any with which I am acquainted in that it requires no expensive apparatus and is so simple in its operation that attendants of the most ordinary intelligence can easily understand exactly how it works and keep it going. A catheter a little longer than the drainage-tube and about half of its diameter, sufficiently large so that it itself can not readily get clogged, is introduced through the drainage-tube previously described so that

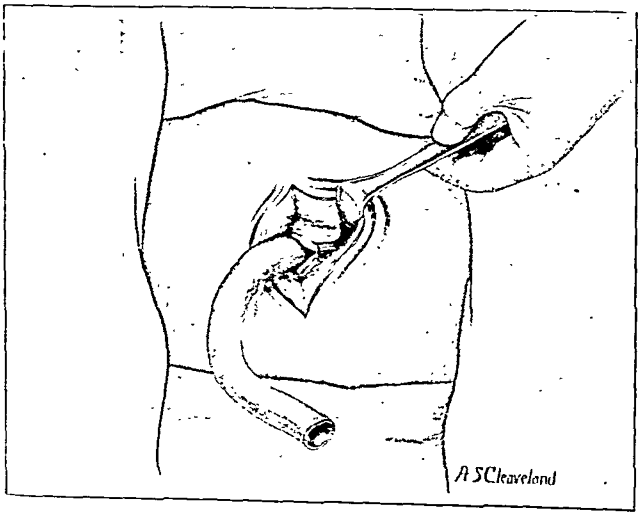

Fig. 8.—The bodies of the recti muscles brought together with a catgut stitch at the upper angle of the wound.

the eye of the catheter reaches just about 1 cm. beyond the proximal end of the drainage-tube. The irrigation through this may be continuous or interrupted. I find it best usually to commence with interrupted irrigation. Nurses are apt to think that when a system of continuous irrigation is used it watches itself, and I find that I get for the first twelve hours much better and more satisfactory service from them if I have them use a hand-syringe or an irrigator at low pressure to keep the tubes clear, injecting slowly a hot, normal salt solution every ten minutes, continuing the injection until the fluid returns reasonably free of clots. After the end of the first twelve hours I employ continuous irrigation. It will be found that the solution entering through the catheter always comes out freely through the large tube along the side of the catheter. This tube is sufficiently long to reach over the body of the patient into a sterile pus basin which is kept up against one of his hips. He is thus kept perfectly dry during the first forty-eight hours, when the large tube is to be removed and a similar smaller tube inserted into the bladder in its place, there to remain for twenty-four to forty-eight hours more. After its withdrawal, smaller tubes, decreasing in caliber, are inserted or not according to the indications of the case.

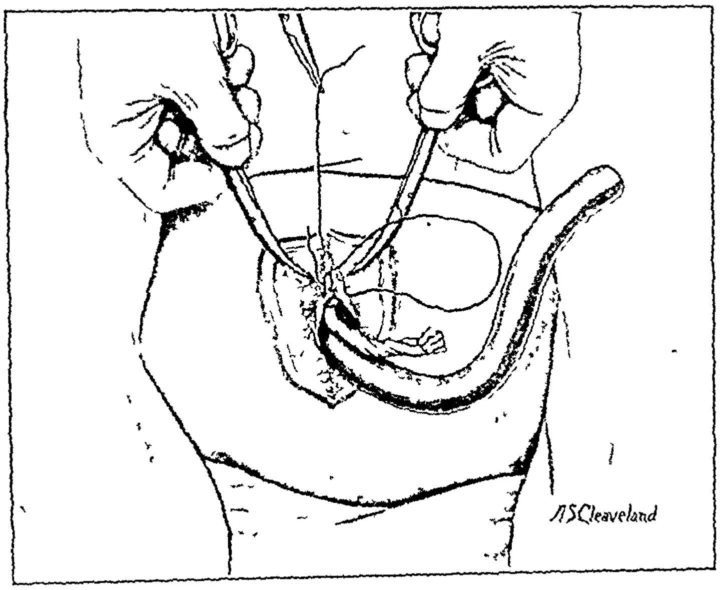

Fig. 9.—Closure of the sheath of the rectus on one side with continuous suture of the baseball type.

The wound which is left after this operation does not close originally any quicker than that left after the longitudinal incision, but it is a funnel-shaped wound from the skin to the bladder, and everything is within sight. The opening in the bladder, being made at its highest point, is readily reached, and there is no tendency for the wound in the skin to close before that in the bladder. There is no weakness in the abdominal wall afterward. The scar that is left when the wound does close is good, firm and solid, and if, for any reason whatever, one is obliged to open the bladder through such a scar, one always knows where the peritoneum is and does not have to worry about opening it accidentally.

I never have been able to understand why suprapubic cystotomy is regarded by the surgical world as a grave operation. I am very certain that the mere opening of the bladder, in the manner which I have described, should not of itself be the cause of death of anyone. Patients may die after such operations from the causes which gave rise to the necessity for the operation, but not from the operation itself, when it is done with due regard to the protection of the areolar spaces about the bladder and the prevention of postoperative hemorrhage from blood-vessels within the muscular coat of the bladder wall, which cannot take place when the bladder is before the operator so that he can see these blood-vessels, pick them up and tie them when he incises them.

602 Lissner Building.

### ABSTRACT OF DISCUSSION

Dr. W. T. Elam, St. Joseph, Mo.: Dr. MacGowan's method is different from the one I have used, although I make the transverse incision through the skin and subcutaneous fat. He divides the deep layer of the superficial fascia transversely. Instead of making my incision across the suprapubic region with the convexity upward, I make the convexity downward, following the suprapubic abdominal fold. I do not know that that makes any particular difference, but my flap recedes upward nicely. Then I make my incision, through the fascia longitudinally with the body, in the median line; I know that this is a method by which I can easily enter the bladder, and work more satisfactorily. I really do not see that it could be improved much by making the transverse incision through the fascia. However, I intend to try Dr. MacGowan's method.

I use this incision frequently in intrapelvic work in women. A year ago I had a case of double inguinal hernia in a man who needed a prostatectomy. I did the operation in that way, and I have since followed it out in that way both in the fat and in the lean. I did a herniotomy on the right side and a suprapubic prostatectomy at the same time.

Dr. MacGowan's system of drainage is, of course, as satisfactory as any could be. I have been in the habit of using the continuous irrigation from the beginning. I frequently instruct the nurse to start the irrigation through the suprapubic tube and connect a retention catheter introduced per urethram into the bladder, and then within a short time reverse it. I keep that up during the first twelve hours in order, if possible, to prevent, dislodge and remove clots.

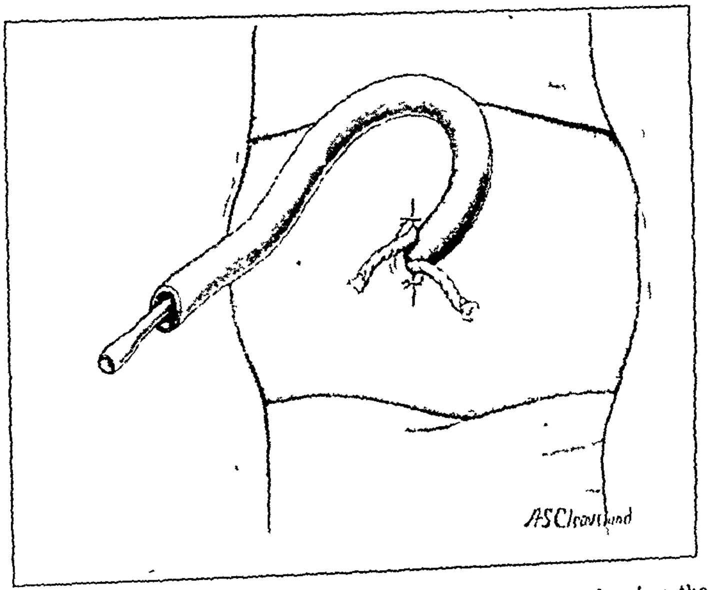

Fig 10.—The wound closed, drainage-tube in place, showing the catheter introduced through the drainage-tube for the purpose of irrigation.

Those who have done suprapubic cystotomies by making the incision vertically through the skin will be much gratified by the change in making a transverse incision through the skin and subcutaneous fat, and perhaps Dr. MacGowan's additional transverse incision through the deep fascia may make the field of operation still easier of access.

Dr. M. Krotoszyner, San Francisco: I am pleased to hear that Dr. MacGowan has not given up spinal anesthesia, which I also use in selected cases and which I consider a safe and efficacious method, especially for prostatics. In a few cases, in which on account of the patient's poor condition even spinal anesthesia did not seem to be practicable, I have opened the bladder under local anesthesia with gratifying results. I use a 0.5 per cent. solution of novocain, to each 10 c.c. of which is added one drop of epinephrin. A rhomboid figure is described by infiltrating the bladder region above the pubes, in the center of which the incision is made. This method of anesthesia seems to be particularly indicated for the purpose of rapidly opening the bladder as the initial step in the two-stage prostatectomy.

Dr. G. G. Smith, Boston: In order to get at growths in the very base of the bladder or in the prostate and so that we can see what is going on at the prostatic orifice, it is essential to carry the incision well down to the pubic bone.

I should like to ask Dr. MacGowan whether that lower edge of the rectus fascia does not prevent one from getting down into the pelvis.

Dr. A. L. Chute, Boston: I should like to ask Dr. MacGowan if he thinks that constant irrigation is essential. I have never had any trouble with clotting, and it has always seemed to me that the continuous irrigation tended to keep up the bleeding. I should like to ask him if he has had any trouble in that way. It seems to me that the bladder distention ought to open up the vessels and cause more bleeding. The other method works satisfactorily. When continuous irrigation is used, moreover, you are not able to estimate the amount of urine. If the patient is in bed it seems to me it is essential to know how much urine he is excreting, and I do not see how that is possible with continuous irrigation.

Dr. Granville MacGowan, Los Angeles: I think you refer to the incision that I saw Cabot make in Boston this year. What struck me most about that incision was that it was so unnecessarily large. It is easy to obtain everything you desire without it. I do not know how many bladders I have opened suprapubically, a thousand at least in my lifetime, and I have tried all methods to make it easy and safe. One can pull the bladder up and out on the abdominal wall through the incision which I have recommended. It is not necessary ordinarily to see the mouth of the bladder, but, if it should be desired to see it directly with the eye, the lower flap of this wound can be pulled down with a retractor after the central tendon is slightly snipped along under the sheath of the rectus muscle. I have removed tumors from the bladder extraperitoneally and intraperitoneally through an incision of this kind. You can get more room by going out further on the fascia, even out beyond the rectus muscles, if it is desired. The edges pull wide apart readily. There are a few cases in which I should prefer the incision which Dr. Cabot uses. It is surprising how much can be done through a small incision made transversely, and, if a small incision through the skin and fascia gives all the room necessary for an operation, why make a larger one? If a larger one is needed, it can always be made.

It has been my unfortunate situation during the whole progress of my surgical career to be dependent on myself. The surgeons who are in large hospitals have at all times skilled interns to look after their cases. Getting up in the middle of the night to take clots out of a bladder is probably something that many of you have been called on to do. When a surgeon has to nurse the cases himself, continuously watch them, or have them looked after by persons who are not trustworthy and skilled, he spends a great many anxious nights if he does not have some way to prevent the accumulation of clots in the bladder. The only sure method that I know for preventing such an occurrence is the procedure of Dr. Freyer, who sticks in an extraordinarily large tube, so that if there is tenesmus from the clots the bladder muscle cannot close. This very large tube, or my own, which is just as efficient and much more comfortable, prevents its closure. Continuous irrigation by the drop method is a great boon to the patient, to the nurse and to the surgeon. The nurse knows practically what she is doing, the patient does not have excessive hemorrhage and the surgeon does not lose his rest. It does not seem to me that it is at all necessary to know how much urine the patient is passing. If the eye is trained, a good observer can tell the minute he comes into the room of a man who has been operated on if there is any lack of kidney function by the general look of his face, and an examination of his tongue; the latter always waves the danger flag.

When after operation the bladder is sewed up tight—I will confess that I have been venturesome enough to do this a few times after prostatectomy and do it successfully, though I should not like to recommend such a practice in general to surgeons—an accurate account of the fluid which comes out of the bladder can be kept, but even then you do not know how much is blood and how much is urine, and you have to squirt water continuously through the catheter to keep it open. If a tube of the kind that I have described here is used, you will know how much fluid has gone into the bladder, because the nurse keeps track of it, and you will know how much comes out of the bladder, and you can deduct one from the other and have a fairly accurate idea as to how much urine the patient has passed.

---

# VASOSTOMY—RADIOGRAPHY OF THE SEMINAL DUCT *

WILLIAM T. BELFIELD, M.D.
CHICAGO

Vas and vesicle usually accommodate from 4 to 6 c.c. of a non-irritant liquid, such as 5 per cent. argyrol solution, injected through a scrotal vasostomy. None of the solution escapes through the ejaculatory duct until vas and vesicle are filled, because this exit is closed by a sphincter. This muscle yields to overfilling of the seminal ducts, the solution passing into the prostatic urethra and thence usually backward into the bladder, but occasionally forward into the anterior urethra, escaping at the meatus. An unlimited quantity of solution may thus be used to irrigate vas, vesicle, ejaculatory duct, prostatic urethra and utricle; and this irrigation may be repeated at the discretion of the operator.

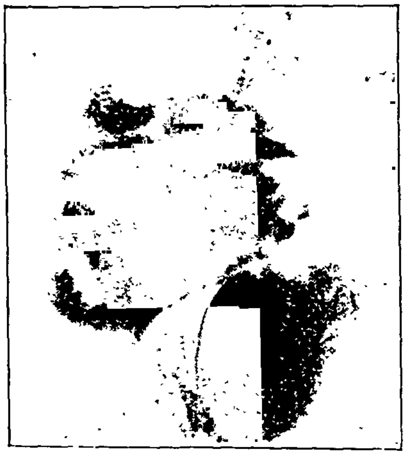

Fig. 1.—Pus infection of vesicle; gleet. For this and the following radiograms, vasa deferentia, seminal vesicles and ejaculatory ducts were injected with collargol solution through vasostomy.

For days after such filling of the seminal duct, peristalsis of vas and vesicle occurs, shown by the constant presence of argyrol in the urine, and sometimes demonstrable through the urethroscope as an intermittent discharge from the ejaculatory ducts. Since this occurs without subjective perception, peristalsis must be regarded as a normal function of the seminal, as it is known to be of the urinary, duct; and the prostatic urethra as the natural catch-basin for the seminal duct, as is the bladder for the urinary canal.

Retrograde urination, that is, the escape of urine through the vasostomy incision when a strong desire to

---

* Read in the Section on Genito-Urinary Diseases of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

urinate was resisted by the patient, has been observed in three of my cases; in two of these, argyrol solution injected into the bladder was forced through the scrotal incision, proving the source and course of the clear fluid previously observed to issue from the cut. Two of these patients had suffered from frequently recurring epididymitis during several years following a gonorrhea; in each the corresponding ejaculatory duct was patulous and easily catheterized. Although this passage of urine from the urethra into the vas seems hitherto to have been unobserved except after operations on the prostate (by Voelcker in two operative cases), yet it seems probable that such retrograde passage of urine into the seminal duct may be the not infrequent cause of recurrent epididymitis and vesiculitis following gonorrhea, as in these cases.

The normal peristalsis of the seminal duct explains certain hitherto obscure phenomena, including the phosphaturia so frequent in the subjects of sexual neurasthenia. These men usually exhibit an infection of the vesicles with hypersecretion and active peristalsis of their contents. Since the vesicular secretion is known to precipitate lime-salts when mixed with urine, it is apparent that the constant discharge of such secretion into the prostatic urethra and thence into the bladder can throw the lime compounds of the urine out of solution in the bladder, causing phosphaturia. That this was the correct explanation in two patients I proved by catheterizing both ureters while the urine in the bladder was cloudy from undissolved lime-salts; from these catheters clear urine escaped. Blood and pus mixed with urine may be derived from the vesicles.

Anastomoses between the dilated extremity of the vas (ampulla) and the associated vesicle are not rare. Since these must furnish direct passage of spermatozoa into the vesicle, this observation seems to prove that the vesicles may be not only secretory organs, but also reservoirs for spermatozoa, contrary to the current assumption.

Experience with vasostomy has shown that sterility may be due to occlusions not alone of the epididymis, but also of the vas and of the ejaculatory duct; also that the absence of spermatozoa from the emitted fluid is sometimes due not to an obstruction of the ducts but to arrest of the spermatogenic function of the testis through an infectious disease, such as mumps or typhoid fever.

That such arrest of spermatogenesis, without impairment of sexual power, may be caused by exposure of the testes to the Roentgen ray, and that it commonly exists in cryptorchids and hybrids (for example, the mule) is generally known; but that it may result also from certain infectious diseases should be understood. For the delusion is still prevalent that sexual power is dependent on spermatozoa; and that the absence of these from the semen of a potent man must be due to occlusion of the seminal ducts. The fact is that sperm production may be abolished by the toxins of general infections, such as typhoid, without diminishing the subject's sexual power; he becomes sterile, but remains potent.

In two of my patients a chronic colon bacillus infection of the seminal duct has caused chronic toxemia, shown by continuous high temperature and progressive loss of weight, exceeding 20 pounds in one case. In both patients irrigation of the seminal ducts through vasostomy was followed by rapid return to normal temperature and gradual recovery of usual weight, as well as disappearance of a chronic gleety discharge sometimes tinged with blood.

The juxtaposition of ureter and infected vesicle, already shown to be capable of causing obstruction of the ureter and consequent damage to the associated kidney, is illustrated in some of my radiograms. The ureter is shown to lie approximately over the central axis of the vesicle; the usual text-book illustrations, made from dissections of the dead subject, apparently do not represent the relations existing in the living body.

Infections invading the seminal duct from either end (urethra or epididymis) may produce (*a*) occlusion or (*b*) a patulous condition of the ejaculatory duct. In the former event a closed abscess results; in the latter, vesicle and epididymis are liable to recurrent invasions by infection and even by urine from the prostatic urethra. The result in either event may be a pus-tube with chronic toxemia. This can usually be successfully treated by injecting the vesicle through vasostomy, sometimes also from the urethra.

In medicating the vesicle through vasostomy, a preliminary injection of some non-irritating liquid, such as 5 per cent. argyrol solution, should be made to test the patency of the entire seminal canal. Should this reach the urethra in a few minutes (shown by blackening of the urine), collargol solution, 1 to 3 per cent.,

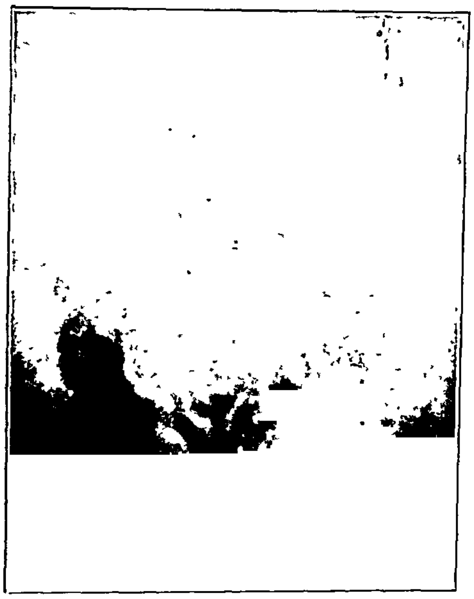

Fig. 2.—Colon bacillus infection of vesicles; chronic toxemia.

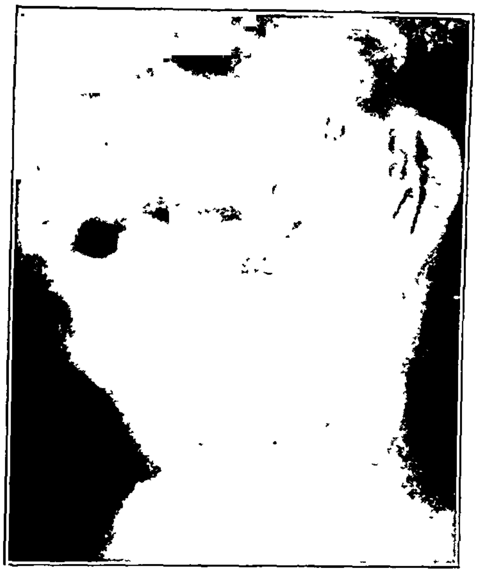

Fig. 3.—Pus-tube on the right; tortuous vas on the left side.

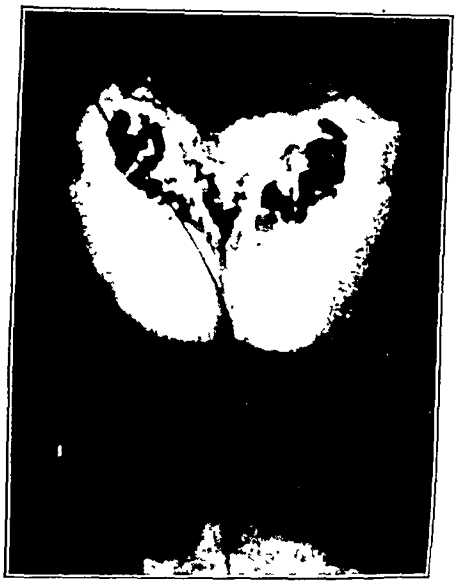

Fig. 4.—Bilateral gonococcus infection; stiletted catheter in right ureter.

may be immediately injected. If the argyrol does not appear in the urine, the more irritating collargol should not be used; for it will be regurgitated into the scrotal tissues around the cut, and there produce a tender induration which is slow to disappear.

The radiograms were made by Dr. Potter and Mr. Ball of the Presbyterian Hospital, and Drs. Case and Van Horn of St. Luke's Hospital, Chicago.

32 North State Street.

# TRANSPLANTATION OF THE TESTICLE *

VICTOR D. LESPINASSE, M.D.
CHICAGO

The first experimental work on transplantation of the testicle was done by Berthold[1] in 1849. He used completely castrated roosters and transplanted the testicle into the abdominal cavity. The transplanted testicle grew, maintained its peculiar character as a sexual organ, and the male habits of the chicken continued.

Other investigators have confirmed this result in chickens. In frogs, Herlitzka[2] transplanted testicles into the peritoneal cavity, and found that they degenerated and became absorbed.

Meyns[3] worked with frogs and implanted parts of the testicle into the dorsal lymph-vessel of the frog and found that these transplants grew and developed new mature spermatozoa.

The size of the transplanted organ has a great deal to do with the success or failure of the operation. If the testicle is transplanted *in toto,* it is almost certain to necrose. If it is cut into thin slices from 1 to 2 mm. in thickness and then transplanted into a vascular bed, such as in the substance of a muscle or in the liver, it will grow. In frogs and chickens the spermatogenic cells retain their function and produce spermatozoa. In warm-blooded animals, the spermatogenic function seems to be lost and the spermatogenic cells disappear in less than thirty days. The Sertoli cells and the Leydig cells, however, do not degenerate but seem to maintain their life and function.

## EXPERIMENTAL WORK

In the first group three adult dogs were castrated and at the same time their peritoneal cavities were opened. Dog 1 had the two testicles from a week-old puppy dropped free into his peritoneal cavity. Dog 2 was treated in the same manner. The spermatic cord and the tunica vaginalis testis were cut away from the puppy testicles, but the epididymis was left attached to the testicle. In Dog 3 the two puppy testicles were wrapped up in the omentum. These dogs were killed six weeks after the operation. The peritoneal cavities were explored but no trace of the transplanted testicles could be found.

In the second group adult dogs were castrated. The testicles freed of the epididymis, cord and tunica vaginalis testis, were then cut in slices from about 1 to 2 mm. in thickness transverse to the long axis of the organ. The central slice, which was the largest, was then taken and placed among the fibers of the rectus abdominalis muscle. These animals were killed in six weeks' time and the transplanted tissue examined. It had shrunk to from approximately one-quarter to one-third the original mass, and had changed to a yellowish color. In some of the dogs the transplant could not be found at all.

Experimental transplantation of the testicle with blood-vessel anastomosis is practically impossible by either a suture method or magnesium ring method of blood-vessel anastomosis applied to the spermatic artery.

The ideal method is that of patching—removing the section of the abdominal aorta, baring the opening of the spermatic artery, and removing the piece of the vena cava, baring the outlet of the spermatic vein.

My search of the literature revealed no experimental work done by this technic. There is, however, one human case on record by Hammond and Sutton[4] of Philadelphia, who operated by making an end-to-end anastomosis of the spermatic artery and vein. This case was an apparent technical success, but the ultimate result was a marked atrophy of the transplanted testicle. The person into whom the testicle was placed has one sound testicle, and hence it is impossible to determine the functional value of the transplanted organ.

It is a generally current opinion that a graft of an organ has a better chance to grow in an individual that needs the secretion from this organ than in one with a normal organ already.

## REPORT OF CASE

A man, aged 38, consulted me in January, 1911, to find out if anything could be done for the loss of both testicles. One testicle which had been retained was removed during a hernia operation; the other had been lost by an accident about two years previous to his consultation with me. He was unable to have intercourse, which was his chief reason for coming to me.

A testicle from a normal man was easily obtained. In fact, I was surprised at the number of testicles that are available for transplantation purposes.

The two patients were anesthetized at the same time, and the recipient prepared as follows: The scrotum was opened high up and a bed prepared in the same way as we prepare the bed for the reception of an undescended testicle. Hemostasis was carried out with great care. Another incision was made over the rectus abdominalis muscle; this incision was carried down through the skin and fascia. The fibers of the rectus muscle were exposed and these fibers separated by opening an artery forceps plunged into the muscle. Hemostasis was carried out and then the testicle to be transplanted was removed. It was immediately stripped of the epididymis, cord and tunica vaginalis, and then sliced transversely to its long axis, these slices being approximately 1 mm. in thickness. The central slice and the one next to it were taken out and placed among the fibers of the rectus muscle. Another slice was placed in the scrotum. The wounds were closed without drainage and healed by first intention throughout.

On the fourth day after the operation the patient had a strong erection accompanied by marked sexual desire. He insisted on leaving the hospital to satisfy this desire. The desire and power of erection have continued for two years. It is now two years and six months since the operation, but I have not seen the patient for six months.

## CONCLUSIONS

Transplantation of the testicle is a perfect operation in frogs and chickens; spermatogenesis and sexual characteristics are preserved. In guinea-pigs, rabbits and dogs the results are variable. Some experimenters report that there is no success at all; others assert that the interstitial cells remain and functionate. In the two human cases that have been tried to date, the one with the blood-vessel anastomosis was certainly a failure as far as spermatogenesis is concerned; but the interstitial cells may be and probably are present.

In my own case the result clinically has been absolutely perfect. The man has regained his sexual powers completely, both as to desire and as to ability to perform. Furthermore, these powers have remained present for two years.

## ABSTRACT OF DISCUSSION

### ON PAPERS OF DRS. BELFIELD AND LESPINASSE

Dr. E. O. Smith, Cincinnati: A few years ago when Dr. Belfield told us of his treatment of the seminal vesicles through the vas deferens, most of us were somewhat skeptical as to the injected fluid getting into the seminal vesicles. Having taken advantage of the Roentgen ray, we now know that the fluid does go from the vas into the seminal vesicles. The operation of injecting the seminal vesicles is a simple one and can be done under local anesthesia. I use anesthesia only in the skin; I use no anesthetic in the spermatic cord or vas. Colic or severe pain following the injection of collargol has been mentioned as due to blocked ejaculatory ducts. That, of course, would explain some cases, yet one of my first patients injected for radiographic purposes, had a most severe colic, notwithstanding the fact that he passed the collargol through the urethra, a few minutes after the injection of the seminal vesicles. This colic lasted for several hours, and was so severe that morphin had to be given hypodermatically. In this case the collargol regurgitated through the incision in the vas into the scrotum. There was a thickening and hardening of the parts, due to the inflammatory process resulting from the irritation of the collargol, but there was no infection.

The relation of the ureter to the vesicles is, I think, best studied on the cadaver. My observation has been that the ureter enters the bladder near the upper pole of the seminal vesicle. The ureter passes diagonally through the bladder, and the ureteral orifice in the bladder would show a little farther down on the seminal vesicle in the roentgenogram. In one or two specimens that I dissected the seminal vesicle extended probably three-quarters of an inch above the ureter overlapping it.

We have found some interesting anomalies in the seminal vesicles in our post-mortem dissections. One was completely double on both sides in the same person. By that I mean that, instead of a single tube with the saccules on the side, we found two complete seminal vesicles on each side joined only at the lowest part.

I think one of the results of this roentgenographic work will be therapeutic. I believe that a great many of these old chronic cases will be cured by one injection of strong collargol solution. Perhaps some of the type of cases that we have been draining surgically can be relieved by this simpler method. One of our first patients for roentgenoscopy was a man who had been treated as a neurasthenic for a long time. We found by examining the seminal vesicles through the rectum that there were some abnormalities, tenderness, etc. No bacterial infection was found in the expressed contents of the seminal vesicles; yet the neurasthenic symptoms and pain disappeared after one injection of the collargol. I therefore believe that we shall soon be in a position to recommend a single injection of a strong solution of collargol as a therapeutic measure. In case this fails we can then resort to the more radical treatment of surgical drainage.

Dr. V. D. Lespinasse, Chicago: Last winter I had two interesting cases of vesicular infection. One of them was in a man whose condition was originally diagnosed as grippe, then as rheumatism. Finally he complained of a little urinary disturbance. He was a man about 55 years of age. He had a very slightly enlarged prostate. He claimed that he never had had gonorrhea, but he had a distinct bilateral seminal vesiculitis; the vesicles were enlarged and tender. I wanted to open up the vas, but was refused.

The other patient was a man I treated some eight months ago for a vesiculitis. He complained of slight pain, particularly on ejaculation. He apparently made a recovery. He went to work, and had attacks of colic. A doctor told him he had a stone in his bladder and gave him some morphin, which quieted his attacks. When he came back to me I suspected that the stone was not in the bladder. I performed cystoscopy and found no stone. I put my finger into the rectum, and as soon as I touched the vesicle he said, "There it is." I opened up the vas, and where I exposed it, it was dilated. The lumen was about as large as the lead in a pencil. As soon as incision was made a light, brownish fluid came out. After a few minims of that had passed out the pain was relieved. A few days later I injected the vesicle and the patient had a return of pain. The brownish fluid continued to drain for ten days. The patient was well when I left home yesterday.

Dr. William T. Belfield, Chicago: The spasmodic contraction of the seminal vesicle—spermatic colic, as it is called—has surely in one case been mistaken for renal colic. Roentgenoscopy was performed and no stone was found. Nevertheless the surgeon opened the kidney without finding the stone or relieving the spasm. Some time afterward the patient came to me. He had a history of seminal vesiculitis following gonorrhea prior to his supposed renal colic; opening the vas and injecting the vesicle relieved him. I reported that case some years ago.

Another patient was operated on for appendicitis because of vesicular pain; another was about to be operated on, but declined. So I fancy we have quite a large clinical field here which we are just beginning to explore.

The case of Dr. Lespinasse is certainly interesting. The transplantation of both testicles and ovaries has been worked out on animals, and in the case of ovaries on human beings. Tuffier of Paris has a list of cases in which he has transplanted ovaries with a restoration of the menstrual function. On this operation on the male, so far as I know, there is no literature whatever. Dr. Lespinasse's case, therefore, acquires extreme interest.

Dr. V. D. Lespinasse, Chicago: Tuffier's work was on ovaries transplanted into the abdominal wall. One very important point in the technic is that the ovary should be transplanted with the pedicle or hilum toward the muscle. Apparently if he put the hilum out toward the skin the ovarian graft did not seem to take. That is the statement he makes. My experience with ovaries is nil. Perhaps if we are a little more careful in our technic, we can really get some results that are worth while.

**Ostwald's Theory of Genius.**—"If we bear in mind the well-known laws of heredity discovered by Mendel and de Vries, we know that every descendant is a mosaic of those qualities which have been transmitted to him partly by the father and partly by the mother. In the face of this fact the problem arises how such an unusual personality can be descended from parents of average ability, since it is just from these laws of heredity that we should conclude that another average equipment would result." The answer which Professor Ostwald would venture as regards this problem is this: The portions of the inheritance constituting a new being probably only on rare occasions fit together or harmonize with each other. The adolescent man then applies the greatest portion of his energy in the task of organizing these accidental inheritances for the purpose of common work and harmonious cooperation, and this task uses up the greater part of the available energy, and withdraws it from productive work. It is only in rare cases that the inheritances are so constituted that they fit each other from the beginning, so that the young man has not to expend any energy on the mutual harmonizing of his elements, but can immediately set about his creative work.—*Current Opinion*, London.

# THE OPERATIVE TREATMENT OF HALLUX VALGUS AND BUNION

JOHN D. SINGLEY, A.M., M.D.
Surgeon to the Pittsburgh and St. Margaret Memorial Hospitals
PITTSBURGH, PA.

The etiology and pathology of this distressing affection are well known. Though it is objectively trivial, not dangerous to life, its subjects are frequently more grateful for relief than are those on whom some life-saving operation has been done.

Numerous methods of operation have been devised and practiced, notably those of Barker, Hueter, Riedle, Weir, Fowler and Mayo. In all, except that of Fowler, the approach to the joint is made from the inner side of the foot, which places the scar in a position where it will be subject to pressure from the shoe. Mayo[1] states that this is but a theoretical objection and that practically it causes no trouble.

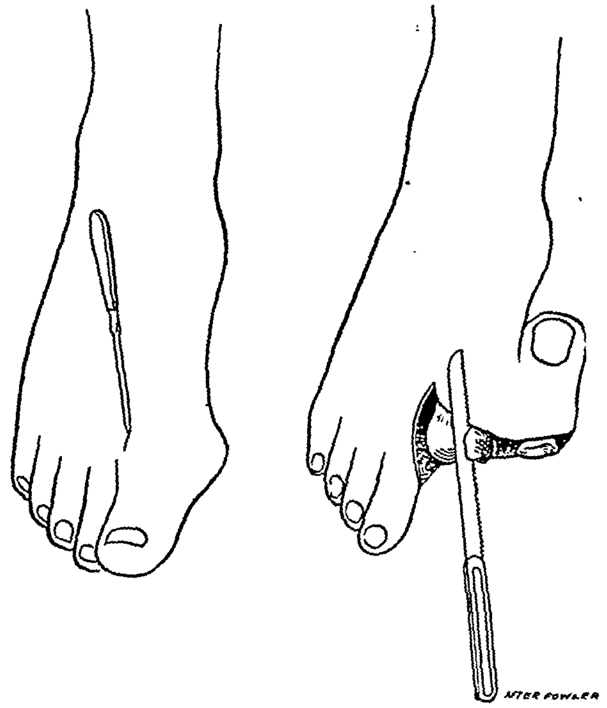

Fig. 1.—Fowler's incision for hallux valgus; to be made by dissection, not transfixion, close to outer side of first metatarsal bone; reversal of great toe. Case of moderate degree is shown, requiring removal of but a portion of metatarsal head.

The method of Fowler[2] as modified by me possesses certain advantages which may be summarized as follows:

1. The incision is in a location where, even on theoretical grounds, it cannot be objectionable.
2. It affords a much better exposure of the diseased ends of the bones than any other method and permits accurate shaping of the new articular surfaces.
3. The joint is opened on the outer[3] side, dividing the shortened external lateral ligament, an important step in avoiding recurrence.
4. Ankylosis is prevented and a new joint formed by the interposition of a fatty-fibrous flap.

### DESCRIPTION OF OPERATION

The incision is made between the affected toe and the second toe, beginning well behind the head of the metatarsal bone on the dorsum of the foot and extending directly through between the metatarsal bones to the plantar surface (Fig. 1). It should not be made by transfixion but by careful dissection, the outer side of the first metatarsal bone being hugged closely. This is important, as will be seen later. The external lateral ligament of the affected joint is freely divided and the great toe forcibly dislocated inward and reversed, the articular surfaces of the metatarsal head and the proximal phalanx presenting (Fig. 1). So much of these surfaces as may be necessary is now removed, preferably with a mounted wire saw (Fig. 2).

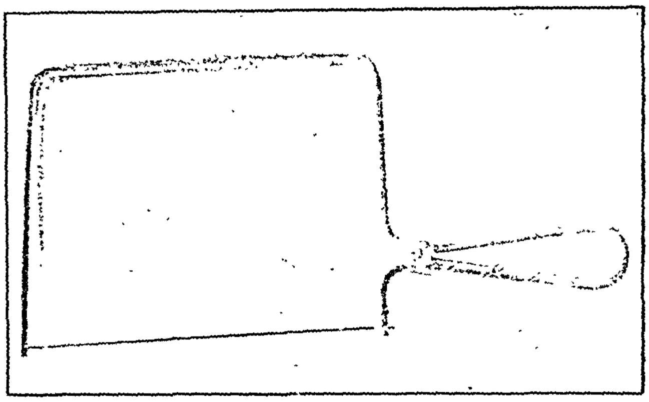

Fig. 2.—Mounted wire saw. The bone ends can be sawed into any shape desired with ease. The saw is cheap and can be procured at any hardware store.

In bad cases the head of the metatarsal and part or all of the base of the phalanx require removal. If so, after the periosteum has been pushed back, the metatarsal is sawed from before backward to leave a convex surface to oppose the base of the phalanx sawed in the same direction with a concave surface (Fig. 3). The plane of these surfaces should be at right angles to the shaft of the bones. Thus we substitute for the ball-and-socket joint a hinge-joint permitting of but little lateral movement.

A fibrous-fatty flap is now dissected up beginning at the web between the toes and having its base at the point of section of the metatarsal bone. This is turned outward over the convex end of the metatarsal and fixed in place on the inner side of the bone with a few catgut sutures (Fig. 4). Abundant tissue is available for this flap, since the intermetatarsal space is much increased in hallux valgus (Fig. 5), and the primary incision lies close to the first metatarsal bone.

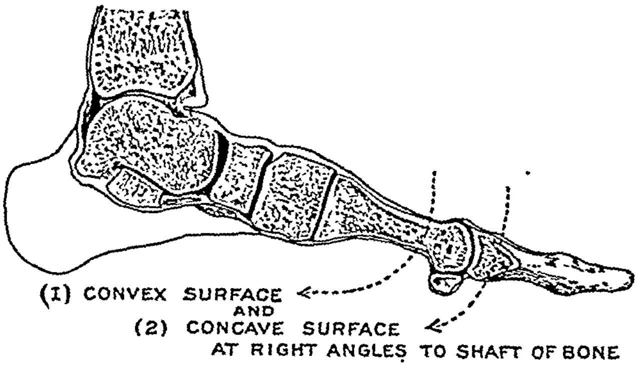

Fig. 3.—Only extreme cases would require removal of amount of bone here depicted. The direction of the lines of bone-section for forming a hinge are indicated.

Instead of this flap, the bursa lying over the head of the metatarsal on the inner side may be used to interpose between the sawed surfaces as in Mayo's operation. The fatty-fibrous flap is preferred, since it is normal healthy tissue, while the bursa is in a state of chronic inflammation (bunion). If the bursa shows much evidence of disease it should not be used for this purpose, but dissected out.

[2] Fowler: Treatise on Surgery, ii, 620.

[3] Throughout this paper the terms "outer," "inner," "external" and "internal" refer to the midline of the body and not to the midline of the foot.

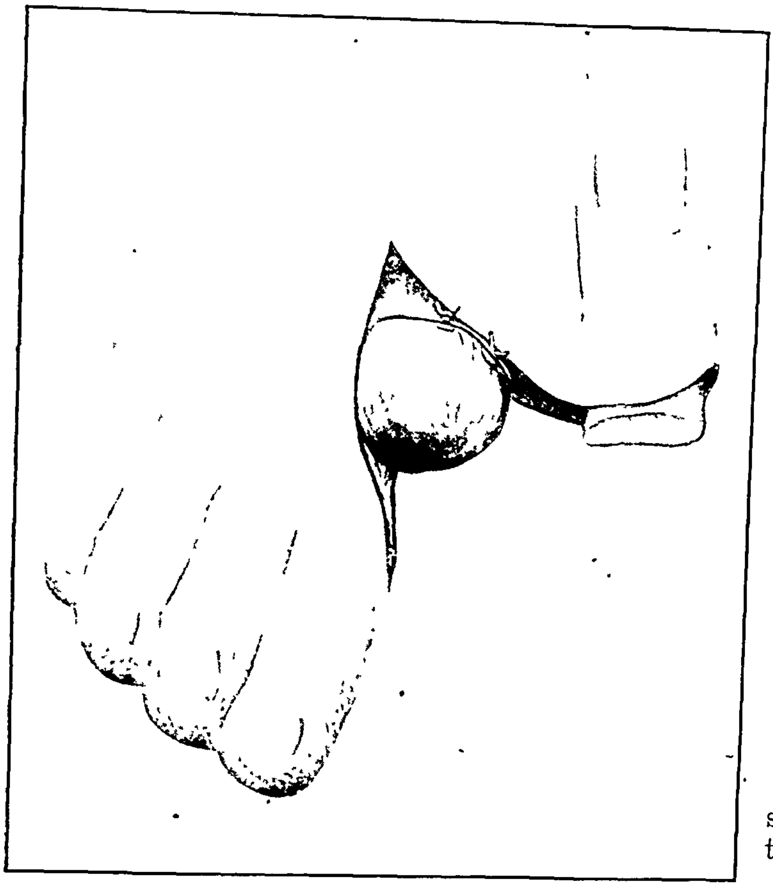

Fig. 4.—The entire head of the metatarsal is supposed to have been removed and the fatty-fibrous flap from the intermetatarsal space turned over sawed surface to inner side and fixed with a few catgut sutures. The artist has improperly represented it in that the covered end of the metatarsal projects too far.

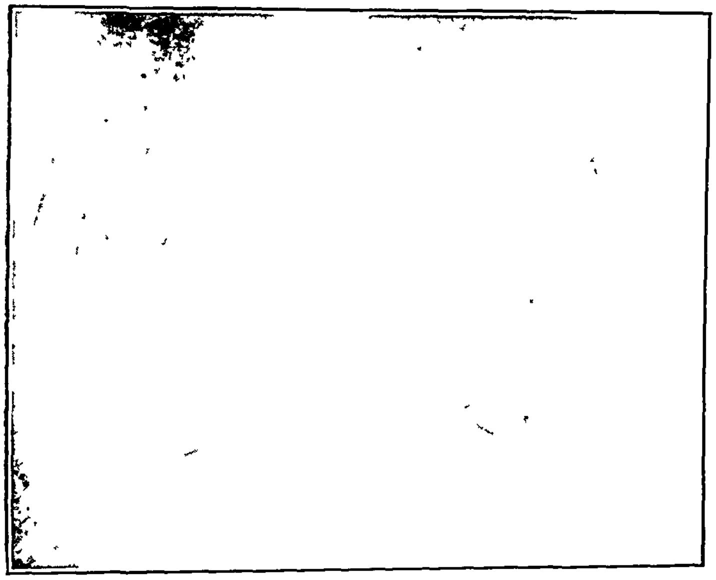

Fig. 5.—Exaggerated intermetatarsal space between first and second bones. Severe case prior to operation. The deformity has been accentuated in right foot by reason of amputation of second toe for hammer toe, done some years before.

The tendon of the long extensor of the great toe is cut and permitted to retract. To attempt to relocate it on the toe (Weir and Mayo) merely invites recurrence of the deformity while it serves no useful function. No one who wears shoes can suffer any inconvenience from the loss of this tendon. The sesamoid bones beneath are not disturbed.

The toe is now returned to its normal position and the capsule of the joint sutured loosely. The incision is closed with three or four silkworm-gut sutures and continuous lock-stitch 00 iodin catgut. Drainage is provided for with a few strands of No. 1 iodin catgut. A wet dressing of 1 : 500 liquor iodi compositus (Lugol's solution) is applied and a shallow cigar-box with top and one end removed is placed over the foot to protect it from the bed-clothes. In lieu of the box, a molded plaster splint (not cast) may be applied along the inner side of the foot to project beyond the toes and to which the great toe is bandaged somewhat inverted.

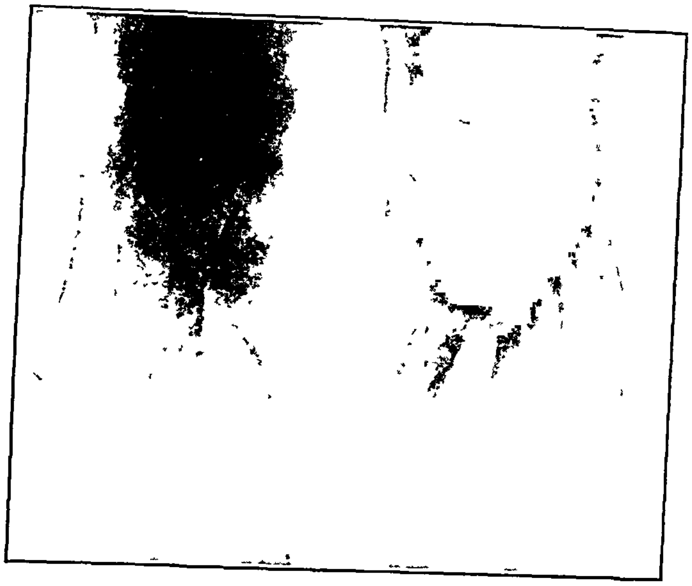

Fig. 6.—Same patient as Figure 5, one month after operation.

Some operators, notably Lovett,[4] seek to obtain firm union and ankylosis after resection of the joint in order to prevent recurrence. This interferes greatly with walking, as a natural gait involves flexion at this joint with each step.

# THE LOCAL SPECIFIC THERAPY OF INFECTIONS *

## II. TREATMENT OF CERTAIN INFECTIONS

SIMON FLEXNER, M.D.
NEW YORK

I propose to lay before you in this lecture the results already obtained by the method of local specific treatment of infection. They are derived partly from experiment and partly from experience with human cases of disease, and they relate chiefly, but not exclusively, to the infections of the membranes of the central nervous system which have formed the starting point of the studies on which the method has come to rest. It may be said, however, that the employment of the method is not limited to the cerebrospinal cavity, although the full extent of its application has still to be worked out.[1]

The reasons are perhaps obvious for utilizing the infections of the meninges as the point of first departure.

---

[4] Lovett: Keen's Surgery, ii, 565.

* This is the second of two lectures which as here presented are based on the Harben lectures of 1912 given before the Royal Institute of Public Health, *London*, and the Trimble Lectures of the Medico-Chirurgical Faculty of Baltimore of 1913. The first lecture appeared in The Journal, Aug. 16, 1913, p. 447.

[1] Flexner: The Biologic Basis of Specific Therapy, Boston Med. and Surg. Jour., 1911, clxv, 709.

The method was originally conceived and put first into experimental and then into clinical practice during the early period of the epidemic of meningitis which visited this country about ten years ago. The general adoption somewhat earlier of the device of lumbar puncture had exposed the meninges in a particularly favorable way to the inspection of pathologic conditions affecting them. By the same means it was rendered possible to produce experimentally in monkeys local infections of the meninges reproducing the corresponding inflammations occurring in human beings which could now be followed closely in process of evolution and even of devolution. It is now an old story that by injecting living, virulent meningococci subdurally into monkeys a fatal acute meningitis is produced; and it is also well known that while the course of this experimental infection is not influenced by intravenous injections of an antimeningococcus serum, it is capable of being arrested and brought under control by direct intraspinal injections.[2]

It is unnecessary to present statistical and other data in order to support the contention that the antimeningococcus serum influences favorably the course of epidemic meningitis. The accumulated experience of the past six years during which its employment has grown in volume and extent until now it is in regular use in practically all countries, has demonstrated its value and made necessary a revision of certain notions concerning its action.[3]

Formerly no fundamental biologic distinctions were made between meningococci; now differences in power of resistance to solution by immune serum are being recognized. Under the influence of the serum injected into the subarachnoid space the diplococci come, as a rule, to lie more and more within the leukocytes; and as recovery from meningitis progresses, even though no antiserum has been employed, a corresponding phenomenon is noted. Indications exist, however, that certain examples of epidemic meningitis in man which respond imperfectly to the therapeutic action of the serum are caused by meningococci resistant or "fast" to the antiserum employed. These strains tend to remain persistently extracellular and to multiply freely in the presence of the antiserum, even under conditions of its high concentration in the meninges. The cases of human infection with the supposedly resistant strains fail not only to respond to the therapeutic action of the antiserum, but also, it can be inferred, more often to ameliorate spontaneously, and thus tend to a fatal termination.

Fastness seems to be capable also of appearing during the specific treatment, since in some instances the meningococci having been at first readily controlled by the injections develop resistance to the serum. This has been noted in certain cases of relapse going on to a fatal termination. Hence, under special circumstances the meningococci seem to acquire a serum-fastness that thwarts its specific action. The original "fast" strain is of uncommon, and acquired "fastness," at most, of occasional occurrence. It is not known whether merely one strain or many fast strains distinct from one another exist in Nature. Information on this point is highly desirable, as is the utilization of fast strains of the meningococcus in the preparation of the antimeningitis serum. Should a true polyvalent serum of high titer carrying immune bodies for the fast strains be developed it is probable that the mortality percentages from meningitis would come to be decreased still further.

Although at first regarded as doubtful it now appears that fulminant cases of meningitis are not wholly without the sphere of beneficial influence of the serum. This conclusion rests, first, on specific statements of recovery of cases of this kind under the influence of the serum and, next, on the change wrought by it in the mortality from the disease during the first three days of prevalence, which is the period during which the fulminant cases terminate in death.

The age factor affects the outcome of the specific treatment just as it affects spontaneous recovery from meningitis, only its influence is even more marked in the serum-treated cases. The most favorable conditions for the specific treatment are in patients between the ages of 5 and 20 years, and the least favorable ones fall in the period above 30 years. The exact coincidence of the favorable ages for spontaneous recovery and for recovery under the serum treatment indicates that the serum provides artificially the means the body itself employs, when it can fabricate them, to suppress the infection, and that two factors, one provided by the body and the other by the serum, cooperate in the end-result; while the greater number of cases terminating by crisis under specific treatment enforces the same conclusion.

The extension of the practice of lumbar puncture as an aid to the diagnosis of meningitis is serving to reveal the important fact that the influenza bacillus is a not infrequent cause of severe and usually fatal seropurulent cerebrospinal meningitis. The first observation on influenza bacillus meningitis was recorded in 1892, and Wollstein has recently collected from the literature fifty authentic cases, supported by bacteriologic investigation. Among this series of instances, which probably gives no adequate notion of the extent of the disease, the recoveries recorded, if fairly representative, indicate a fatality of more than 90 per cent., or one exceeded only by the tuberculous and pneumococcal infections of the meninges. Among the eight cases that came under Wollstein's attention, there was no survival. This affection, like the acute meningeal inflammations in general, is more prevalent among children than among adults.[4]

Influenzal meningitis is associated in many, if not in all, instances with influenza bacillary infection of the respiratory tract which, at certain seasons, becomes exceedingly frequent in children. The effects of the infection are various and commonly consist of a persistent bronchitis or the more severe bronchopneumonia. The bacilli can be cultivated from the bronchial mucus and, as thus obtained, possess, as a rule, but low virulence for laboratory animals. In these patients the influenza bacilli do not appear in the circulating blood. When the meninges are invaded an acute inflammation is produced, and the bacilli in the cerebrospinal fluid now show marked virulence for laboratory animals and often appear and multiply within the circulating blood.

The cerebrospinal fluid, removed by lumbar puncture, from human patients is always turbid, and deposits, on standing, a yellowish or whitish sediment, the supernatant liquid remaining nevertheless somewhat clouded. As the disease advances, day by day, the fluid becomes more heavily charged with pus-cells until toward the end, and as late as the seventh day of illness, the puncture may yield merely a viscid mass of purulent matter. The number of influenza bacilli present in the fluid is usually large; and the bacilli lie chiefly extracellular among the pus-cells, although a variable, but small, number is usually found ingested by the leukocytes. In morphology the bacilli vary somewhat and in this respect the observer may readily be deceived as to the nature of the bacteria present. While some of the fluids contain the typical, minute rods, others show quite irregular and knobbed or even filamentous bacteria that have little resemblance to the influenza bacillus as seen in recent cultivations. These bizarre or involuntary forms, however, are met in old and exhausted cultures; and when they are recultivated on a suitable hemoglobin medium, they yield the typical minute rods.

[3] Flexner: The Results of the Serum Treatment in Thirteen Hundred Cases of Epidemic Meningitis, Jour. of Exper. Med., 1913, xvii, 553.

[4] Wollstein: Influenza Bacillus in Inflammations of the Respiratory Tract in Infants, Jour. Exper. Med., 1906, viii, 681; Serum Treatment of Influenzal Meningitis, ibid., 1911, xiv, 73; Influenza Meningitis and Its Experimental Production, Am. Jour. Dis. Child., January, 1911, p. 42.

The cerebrospinal fluid removed, by lumbar puncture, from monkeys inoculated by subdural injection with virulent cultures of the influenza bacillus is at first turbid, then purulent, and contains a large number of the bacilli, also chiefly extracellular. The bacilli regularly invade the general blood from this source, from which they can be cultivated during life and after death. The average duration of life of the inoculated monkeys varies from thirty-six hours to several days, but, on the whole, is less than in human patients with influenzal meningitis, who may succumb in three or four days or survive two or more weeks. At necropsy a purulent exudate covers the surfaces of the brain and spinal cord, which is more delicate in the case of the experimental than of the spontaneous disease. The fluid in the lateral ventricles tends to be turbid; and from both sources numerous bacilli can be cultivated.

Hence it appears that in all essential points the experimental approximates closely to spontaneous influenzal meningitis. This fact once established, the question which immediately presented itself was whether the experimental affection could be controlled by means of a specific serum that was introduced directly into the seat of disease by intraspinal injection. By means of ordinary methods, first a goat and then a horse was immunized to the bacilli. It was ascertained that the normal blood contained neither agglutinin nor opsonin for the influenza bacillus. The first cultures injected subcutaneously were non-virulent strains, which failed to give rise to immunity principles. When virulent strains were substituted, agglutinins and opsonins began to appear. After several months' treatment they reached a considerable level, the opsonin always exceeding in quantity the agglutinin produced. The serum lacked bacteriolytic properties. At this juncture it was tested therapeutically.

The serum injections were made at various periods after the inoculation of monkeys and consisted in the injection of virulent cultures, in a previously ascertained fatal dose, into the membranes by lumbar puncture. The earliest period at which the serum was injected was five hours and the latest twenty-four hours after the inoculation. The bacilli had multiplied extensively and leukocytes and lymph had appeared in the cerebrospinal liquid. The bacilli were predominatingly extracellular. Two, three or four cubic centimeters of liquid were drawn off and replaced by the serum. According to the symptoms presented the injection of the serum was repeated after from twelve to twenty-four hours. Usually three or four injections sufficed to arrest the multiplication of the bacilli and to control the inflammation. The first evidences of favorable action on the part of the serum consist in a beginning increased ingestion of the bacilli by the phagocytes and, as shown by diminishing turbidity of the fluid withdrawn by the puncture, of retardation of the course of the inflammation. The symptoms disappeared more slowly than the evidences of infection. With each succeeding injection of the serum the local conditions in the membranes improved: the fluid withdrawn was clearer, contained fewer bacilli and those present were chiefly inside phagocytes; while the colonies developing in cultures were also diminished. The pus-cells, however, might disappear before the last bacilli since the perfectly limpid cerebrospinal liquid, taken from what appeared to be well animals, still yielded the bacilli in some instances. Ultimately they also disappeared entirely.

Let us now follow the events taking place in the blood-stream. The virulent bacilli pass quickly from the meninges into the blood, where they multiply. It is patent that unless the bacteriemia can be suppressed it would be futile to base hopes of success on the control of the meningeal inflammation alone. I have referred to the fact that infection of the meninges in children with influenza bacilli follows, usually, on a previous infection of the respiratory organs. It appeared in the course of the earlier control experiments that in the monkey the reverse effects may take place. That is, the bacilli brought by the blood to the lungs sometimes set up pneumonic inflammation there. It is necessary, therefore, to consider the consequences of the bacteriemia on the local treatment of the meningeal infection. Fortunately, the difficulties surrounding the passage of the antiserum from the blood into the cerebrospinal liquid are directly contrasted with the ease with which the antiserum escapes from the meninges into blood. This discrepancy is explained by the fact that while the fluid on entry is in the nature of a secretion from the chorioid plexus, the escape is by way of the veins in the membranes themselves. While, therefore, it is impracticable to bring the antiserum into the meninges from the blood, the reverse result is readily accomplished. Thus it happens that in such secondary infections of the circulation with bacteria as we are here considering, not only does the suppression of the primary focus of infection stop the eruption of the bacilli, which is the cause of the blood infection, but also the passage of the antiserum from the membranes into the blood arrests their development there.

The experimental results are obviously the beginning, merely, of the attack on the problem of the specific therapy of influenzal meningitis, and they will come to have merely theoretical, or the far more important practical, interest, according as they are in some degree applicable to the infection in human beings. At the outset it should be recognized that often influenzal meningitis is a secondary process that follows on a previous infection usually situated in the respiratory tract. Only experience can answer the question whether the control of the meningeal infection will suffice to save life in view of the influenzal lesions elsewhere present, and whether or not these also are favorably affected by the serum. The anti-influenzal serum is just now being issued for use in man. It has been applied too seldom in the treatment of influenzal meningitis to warrant any deduction but one, namely, that under its influence the bacilli in the cerebrospinal liquid diminish in number and are taken up more freely by phagocytes.

Pneumococcal meningitis, having also been opened up to experimental investigation, may be considered somewhat in the same manner. Meningitis is caused by the pneumococcus more frequently than by the influenza bacillus, and its mortality is certainly no less than in the latter disease. The two affections resemble each other in being secondary rather than primary infections. The pneumococcus infection follows on pneumonia, inflammations of serous membranes and infections of the nasopharynx, internal ear and mastoid cells. In other words, the pneumococcus penetrates directly to the cerebral membranes from an adjacent structure or is brought to them indirectly by the blood.

When a virulent culture of the pneumococcus is injected into the meninges of monkeys an acute meningitis results that presents the chief clinical and pathologic characters of the disease as it appears in man. It corresponds with the spontaneous disease further in ending with rare exceptions in death. While the course of the experimental affection appears to be the same, irrespective of whether the pneumococci are injected into the meninges of the brain or spinal cord, therapeutic tests have shown that the infection following on the former is far more difficult to control than that resulting from the latter. It is probable that in man, also, the early injury inflicted on the brain by the pneumococcus entering directly the cerebral meninges diminishes the chance of recovery.

Many attempts have been made unsuccessfully in the past to control pneumococcus meningitis by indirect and even by direct injections of an antipneumococcus serum.[5] It is quite impossible to tell from the rare recoveries whether or not anything of value was accomplished by the treatment. The case with the experimental disease is quite different. Rhesus monkeys can be made to develop regularly a fatal form of meningitis through subdural inoculation in the lumbar region of a suitably virulent culture of the pneumococcus. The inoculation is followed by an incubation period of several hours, after which the animal gradually falls ill. The symptoms intensify and death results in from twenty-four to seventy-two hours after the inoculation.

The subdural injection of antipneumococcus serum may produce no effect whatever or may delay somewhat the fatal result; it does not prevent it. Whether any or no action whatever is exerted by the serum depends not on the stage of the disease so much as on the particular quality of the serum employed. I referred in the previous lecture to the fact that the pneumococcus is one of the parasitic micro-organisms that flourishes in Nature in more than one form. In fact, it is now known to occur in several independent forms which resemble one another in cultural and differ from one another fundamentally in immunity reactions. It is only when the type of infecting pneumococcus and corresponding immune serum are brought together that any effect whatever is produced on the multiplication of the parasites within the meninges and the steady progress of the disease. Ultimately, even under these favorable conditions, the infected monkeys die. Is it possible by any known means to avert the fatal result? This question can now be answered affirmatively and for the reasons that I shall relate.

The factors considered in the past responsible for spontaneous recovery from infectious diseases consist of the blood antibodies and phagocytes. Probably other elements participate in the process and in special definite chemical substances that are always present in a focus in which tissues and cells are disintegrating. That various cells of the body yield, on extraction, substances capable of dissolving red corpuscles and destroying bacteria and differing markedly from the antibodies of the blood has long been known. Leukocytes contain and give up to solvents thermostabile bactericidal chemicals of considerable potency. A long line of special investigations deals with this subject, the full significance of which is not yet appreciated. The thermostabile bactericidal and hemolytic substances yielded by the cells of the organs on extraction and autolysis are in part identical with the leukocytal bactericides and have been identified as soaps of the higher unsaturated fatty acids.

Considerable significance may attach to this observation. It has long been known that soaps appear in inflammatory foci and in degenerating tissues; and the calcium salts deposited in obsolete necrotic lesions are united, in part, with fatty acids. Recent inflammatory foci contain lipase and, of course, disintegrating leukocytes and tissue elements. The latter yield both neutral and higher phosphorized fats, or lecithin-complexes, from which the lipase is capable of liberating fatty acids. This reaction, moreover, is not restricted to inflammatory foci purely and to cells obviously degenerating and disintegrating. That it takes place in a much more subtle way is shown by observations made on the liver. The normal organ yields less than one-half its fat on simple extraction, the remaining part being bound to the protein so firmly as to require digestion or denaturation of the latter to release it. The liver in phosphorus or toluylendiamin poisoning, on the other hand, gives up its fat to simple solvents, and a part of the fat has already been converted, during life, into glycerol (glycerin) and free fatty acids. The liver in acute yellow atrophy likewise contains an excess of free unsaturated acids, and the lung in acute lobar pneumonia yields both the free acids and lipoidal substance.

The quantity of bactericidal bodies yielded by cells in process of disintegration may be considerable, therefore, so that it may well be that the dissolution of tissue-cells and leukocytes that often results from a local bacterial infection may be not entirely to the advantage of the parasite since the chemical substances liberated themselves exert an injurious action on the infecting bacteria.[6]

The study of the manner of reaction of pneumococcus cultures to oleate soaps has illumined the subject. The effects of sodium oleate are representative of the class of bactericidal soaps. In solutions of from 0.5 to 1 per cent. the chemical rapidly kills the pneumococci, which are converted into a formless viscid mass. In solutions of, say, 0.1 per cent. the pneumococci survive, but they have been rendered more subject to dissolution by autolysis than untreated pneumococci. The acceleration of the autolytic process is so great that a few hours suffice for complete disintegration of the micro-organisms. Still weaker concentrations—say, 1 part of the soap in from 10,000 to 20,000 parts of water—produce no obvious alterations: the bacteria retain normal form, staining and power to grow in cultures. And yet the autolytic reaction is heightened; but still more significant is the fact that the pneumococci have become subject in remarkable degree to serum lysis and particularly to immune serum solution. This phenomenon is of considerable theoretical interest since it shows that a bacterium may be altered by chemical action in such a subtle way that while it retains all its obvious biologic properties apparently intact, it may yet be changed profoundly in its chemical reactions.

[6] Lamar: Chemo-Immunologic Studies on Localized Infections, First Paper: Action on the Pneumococcus and Its Experimental Infections of Combined Sodium Oleate and Antipneumococcus Serum, Jour. Exper. Med., 1911, xiii, 1.

The soaped diplococci exhibit still another profound change. They have lost in some degree their virulence for mice and rats. The retained virulence is, however, always sufficient to cause septicemia and death of the inoculated animals unless, indeed, immune serum has been injected along with the culture. The course of events in rats injected into the peritoneum is instructive: in the control animals the unsoaped diplococci begin to multiply rapidly, there is almost no emigration of leukocytes and death occurs in eighteen hours. The addition of an immune serum alone to the untreated diplococci does not save life. The soaped diplococci suffer, within four hours of the inoculation, a considerable diminution in number; but multiplication sets in later, leukocytes in numbers remain absent from the exudate, no phagocytosis occurs and death results in thirty hours. The addition of a normal serum does not change this result essentially. When an immune serum is substituted, however, the diplococci are quickly suppressed, and no subsequent multiplication whatever takes place; no more leukocytes migrate than in the other instances, but the animals fail to become ill. Hence the conspicuous fact that oleate soaps act in a peculiar manner on pneumococci, rendering them subject to serum lysis not only *in vitro* but equally *in vivo*, and coincidently enabling an immune serum to remove their pathogenic action. This important final action of the immune serum takes place only when there is correspondence between the type of infecting pneumococcus and antipneumococcus serum employed.

Before proceeding to the consideration whether these observations are capable of being put to therapeutic use, let us consider for a moment the question of the manner in which pneumococci disappear from the pneumonic exudate and ascertain whether any analogies with the preceding phenomena can be detected. We know that the diplococci undergo a form of autolysis in the exudate and that they likewise are diminished in virulence, and we have seen that these are equally the effects which soaps produce. The other factor necessary to reduce still further the pathologic action of the parasite is a specific immune serum which is provided by the antibodies that appear in the blood in the course of the pneumonic attack. The theoretical conditions are therefore obviously fulfilled for the bringing about of the dissolution of the diplococci in the affected lungs. There is now presented, however, a serious obstacle to the working out of this relationship. The hemolytic and bacteriolytic effects of the soaps of the unsaturated fatty acids are inhibited by protein matter such as exists in the serum of the blood or of exudates. This inhibition must first be overcome before the lytic action can take place. Just how it is set aside, if at all, within an exudate is not known; but it is worth while to consider factors that may possibly suffice to remove the impediment, among which are the proximity of the bacteria to the nascent fatty acids and soaps, and to suggest the existence there of other chemical substances that may have the effect of removing the protein inhibition. The inhibition can be prevented in the test-tubes and also in the animal body by adding a third constituent of a protective nature, which in this instance may be boric acid. A minute quantity of this chemical prevents the union of soap and protein matter when the latter is not in too great excess.[7]

This finding has made it possible to employ mixtures of sodium oleate, antipneumococcus serum and boric acid in the treatment of established pneumococcus infections. In this way the intraperitoneal inoculation of highly virulent cultures in rats has been brought under a measure of control. The peritoneal cavity, however, because of the variety and complexity of the contained viscera, and the ready isolation of foci of infection impossible to be reached locally, make success in that site, in very small animals, difficult to achieve. Hence, we have again turned to the meninges, the subarachnoid spaces of which are better adapted to the purposes of experiment, with the results to be mentioned.

It is possible to cause pneumococcus meningitis by injecting a culture of suitable virulence into the membranes of monkeys by lumbar puncture. Since the infection set up should, on the one hand, terminate fatally in the controls and, on the other, insure the survival of the animals for two, three or more days, in order to afford average conditions for the operation of the therapeutic agent, the culture and the dose must be accurately worked out. This having been done, it can now be shown that the injection of an optimum mixture of sodium oleate, boric acid and immune serum, by lumbar puncture, into the cerebrospinal membranes is capable of rescuing many infected monkeys, eight, twelve, eighteen and even twenty-four hours after the inoculation and at a time when the number of the diplococci present in the exudate is large and the animals are critically ill.[8]

The effect of the mixture is striking. Within three or four hours of the first injection the diplococci have undergone an enormous diminution in numbers, and phagocytosis, previously entirely absent, has begun to take place. The injections are repeated at intervals of from twelve to twenty-four hours for several days and until all pneumococci have disappeared from the membranes and the fluid has again become clear and limpid. The success of the treatment depends in considerable part on complete suppression of the pneumococci, as shown by cultures and by direct microscopic examination, since the infection in the monkey shows a strong tendency to relapse; and a relapse that is not promptly treated and controlled is quickly fatal. On this account extra vigilance is called for; and the seemingly wholly restored animals need to be kept under close scrutiny for several days longer, the general condition, appetite and temperature being closely observed. As already stated, the antipneumococcus serum alone has proved powerless to bring about recovery.

Monkeys that are inoculated subdurally with pneumococci quickly develop a bacteriemia; and it is of great practical significance that with the control of the meningitis the blood infection also disappears. The number of diplococci that sometimes appears in the blood is so large as to indicate multiplication there; but so long as a secondary inflammatory focus does not arise, this state is controllable along with that of the meningitis. In rare instances secondary pneumococcus pneumonia or even peritonitis arose; in these the bacteriemia persisted

[7] Von Liebermann and von Fenyvessy: Ueber die gegenseitige Aktivierung hämolytisch unwirksamer Stoffe, Ztschr. f. Immunitätsforsch., Orig., 1909, ii, 136. Lamar: Jour. Exper. Med., 1911, xiii, 1.

[8] The therapeutic mixture consists of the following constituents per cubic centimeter:

| | c.c. |
|---|---|
| Antipneumococcus serum (corresponding type) | 0.2 |
| 5 per cent. aqueous solution boric acid | 0.75 |
| 2 per cent. aqueous solution sodium oleate (Kahlbaum's or Merck's) | 0.05 |

The mixture is freshly prepared for each injection; it should, of course, be sterile. The dose injected into monkeys averaged 2 c.c. For man it has still to be worked out, but may be from 10 to 20 c.c. and possibly even more. The usual precautions employed in making intraspinal injections, such as previous withdrawal of cerebrospinal fluid and careful and controlled administration, should be observed.

and there was a fatal issue. In some instances a fatal issue has followed on the dissociation of the spinal and cerebral membranes by means of an impassable exudate at the foramina at the base of the brain. This is the common condition arising in epidemic meningitis that has hitherto defeated the curative effects of the antimeningitis serum and is now being overcome by means of direct intraventricular serum injections.

It is obvious that under the conditions stated sodium oleate exhibits a greater affinity for pneumococci than for either ordinary protein matter or the protein constituents of the cells of the nervous organs; for under circumstances in which boric acid withholds it from the latter it still attacks the micro-organisms. This is a condition relating to all drugs employable as curative agents; they must show greater action on the parasites than on the cells of the organs, else they may do harm rather than good. The oleates thus far have been observed to exert their peculiar action on pneumococci irrespective of race; but they have needed to be assisted by immune serums of strict correspondence in origin with the race of infecting diplococcus. Morgenroth[9] has recently prepared a drug, ethylhydrocuprein, related to quinin, which possesses remarkable powers of overcoming pneumococcus infection in mice. Under its influence, however, strains refractory to the drug arise; and probably rare races fast to the chemical occur in Nature.[10] Because of its high toxicity for human beings, however, the drug is inapplicable to the treatment of pneumococcus infections in man.

A small number of tests of the oleate, boric acid and immune serum mixture have been made on human cases of pneumococcus meningitis and the observations on monkeys so far confirmed as to prove the necessity of employing an immune serum agreeing in race with the infecting micro-organism. When this correspondence is accomplished, the pneumococci within the exudate are diminished rapidly by solution and phagocytosis; when it fails, no action on the pneumococci has been detected.†

The conditions are somewhat different with another group of affections of the nervous system which I shall now discuss. The fact has long been regarded as notable that notwithstanding the origin of tabes and paresis from syphilitic infection those diseases respond so little favorably to antisyphilitic measures of treatment. Partly for this reason and partly because of the characters of the pathologic changes, they have been separated off from the typical varieties of syphilis and placed in a special category of metasyphilitic or parasyphilitic affections, so called. Now that the *Spirochaeta pallida* has been shown by Noguchi[11] to occur in numbers in the brains of paretics and has even been found in the spinal cord in tabetics, this classification calls for complete revision.

In the meantime how is the disparity in therapeutic response of these affections to be explained? First, it may be mentioned that there is growing evidence that salvarsan, injected into the blood, may exert a beneficial influence in tabes, but not in paresis. The evidence is derived partly from clinical improvement and partly from the reductions in the cellular and protein contents of the cerebrospinal fluid, and the diminution of the Wassermann reaction. These changes are in accord with the inconstant and fleeting presence of arsenic in the fluid following the intravenous, but not the intramuscular injection of the drug.[12] Hence it would appear probable that better results still might be accomplished provided the drug could be brought with certainty and in suitable concentration into this fluid. Such a method of application, worked out by Swift and Ellis,[13] offers considerable promise of high therapeutic value.

The pathogenesis of tabes is still unsolved. What seems established is that the lesions of the spinal cord and the clinical symptoms are dominated by pathologic states of the meninges. It is known that in most cases of the disease the cerebrospinal liquid contains the products of irritative or inflammatory conditions existing within the membranes; and microscopic study has revealed areas of chronic meningitis about the radicular portions of the spinal and corresponding portions of cranial nerves. To reach the pathologic processes in the membranes, not in tabes only but in paresis as well, is made peculiarly difficult because not only do we have to reckon with the ordinary conditions of impenetrability of the meninges, but there often coexists also an obliterative arteritis of syphilitic origin.

It is not safe to introduce salvarsan directly into the subarachnoid space, and while neosalvarsan, because of its ready solubility, is less injurious, yet the direct injection of that drug is attended with certain risks.[14] Swift and Ellis have therefore taken advantage of the circumstance that the blood of salvarsan-treated patients is itself curative, and they have employed the corresponding serum, suitably diluted, for intraspinous injection. The results are both promising and striking. The local irritative condition in the meninges becomes quickly diminished, the Wassermann reaction reduced or abolished and the clinical state of the patient improved. These effects follow even when the salvarsanized blood of other persons is employed for intraspinal injection. They are due, therefore, to the local and not to the general treatment.

This method has not yet been applied to the treatment of paresis, and nothing less than a careful and thorough trial can determine its applicability. Certain theoretical facts, however, stand well in the foreground. It is known, for example, that the cerebrospinal liquid provides a means of direct and immediate contact with the structural tissues of the brain.[15] Whatever chemical is introduced into this liquid will inevitably find its way to the supporting elements, the nerve-cells and fibers of the cortex in which the main lesions of paresis are situated. It is in the cortex likewise that the *Spirochaeta pallida* has now been found, from which it follows that this organism can best be brought under the influence of curative agents through the same channel of communication.

† It is obvious that to be practical it becomes necessary to possess a method of rapid identification of the type of infecting pneumococcus. A method of this kind is provided by the agglutination reaction as given by Dochez and Gillespie (A Biologic Classification of Pneumococci by Means of Immunity Reactions, THE JOURNAL A. M. A., Sept. 6, 1913, p. 727). Moreover, it will also be necessary to have available either separate immune serums corresponding to the main biologic types of pneumococcus or an efficient polyvalent serum of high titer.

more active. Whether or not a sac that has once contained a loop of intestine or omentum may spontaneously close cannot be definitely stated. Why peritoneal surfaces become spontaneously obliterated during fetal life and soon after birth is unknown. It is not possible to prove that obliteration can be caused by any artificial means. It is maintained by many, however, that some do close spontaneously. The proportion cannot be even approximately stated, for it is quite impossible to keep these patients under observation. From the evidence at hand it is more likely that even when the hernial contents cease to descend the canal remains patent and is always ready to be filled whenever there is a weakening of the muscle or an unusual increase in intra-abdominal pressure. Stiles has demonstrated that in the so-called cures the sac remains patent and only awaits favorable conditions for the reappearance of the hernia. Kovacs[7] believes that it is but rarely if at all that a hernia becomes spontaneously cured.

If a hernia is allowed to go untreated, strangulation with its attendant dangers is always possible. Usually even strangulated hernias can be reduced after a time and death from strangulation is very rare.

### PROGNOSIS UNDER TREATMENT

Treatment by means of the truss does not materially alter the course. The purpose of a truss is to retain the hernial contents within the abdomen and permit the surrounding tissues to regain their elasticity. There is nothing in the physiology or adaptive pathology of the peritoneum to warrant us in the hope that keeping the canal empty by means of a truss will cause the sac to become obliterated. That the pressure of the truss may cause sufficient irritation of the opposed surfaces of the sac to cause them to become adherent is of course beyond the possible. At the same time it is necessary to give respectful attention to the palliation of hernia by means of the truss. Two recent books on surgery in childhood favor this treatment within rather wide limitations.

It has been estimated that approximately 25 per cent. of patients treated with the truss are temporarily cured by it. That is to say, after being worn for several years the truss may be left off without a return of the hernia for a period of years. Subsequent history is difficult to obtain, for it is quite impossible to maintain a record throughout the patient's lifetime, and those who advocate truss treatment make no attempt to answer the question as to the future of the so-called cured cases. One meets, however, patients with hernias in later life who give a history of hernia in childhood, which had been apparently cured by a truss. One is therefore inclined to look on the curative value of the truss with skepticism.

The truss has been used for infants only a comparatively short time. It was formerly thought inadvisable because of the disposition to favor troublesome eczemas and even fatal gangrene. Ravoth,[8] as late as 1868, found it necessary to combat this view. As a matter of fact, however, if one entertains seriously the notion that a sac can be obliterated by the pressure of a truss, troublesome excoriations and even graver lesions are very likely to appear. The younger the child the more difficult it is to keep a truss applied.

Most practitioners content themselves by the use of the well-known skein truss. These more often hide rather than retain the hernia. In fat babies spring trusses are kept on with great difficulty and elasti trusses with perineal straps are apt to cause troublesom excoriations. In thin, emaciated babies better result may be obtained. After from three to six years, depending on the activity and build of the child, a truss can b made to retain the hernia with a certain degree of efficiency. The abuse of the truss comes in allowing the child to bear the discomforts of a steel band carrying a pad which rests somewhere in the region of McBurney's point. This gives a false sense of security and unnecessarily punishes the child, especially when a strong spring is used with the idea of obliterating the sac by pressure. The whole development of the child, mental and physical, may be retarded by a troublesome hernia or an ill-fitting truss.

Operative treatment has gradually come more into use in recent years. This is due to the more general appreciation of the anatomic relations of hernia and to a perfected technic in its radical cure.

Palliation is still largely practiced chiefly by two classes of persons; those who are opposed to operation by principle and those who employ palliation from necessity, either because the parents do not consent or because facilities are not available. Those who oppose radical cure from principle may be divided into two classes, those who still believe that hernia may be cured by the truss and those who have met disaster in radical treatment. Among the latter may be mentioned Grunert,[9] who had three deaths in thirteen patients. He advises against operation during the first three years.

Palliation will still retain a large number of advocates because of necessity, especially in regions in which operative facilities are not available.

A considerable number of operators advise operation in all or nearly all cases. Perhaps Stiles[10] has spoken with the clearest vision and the greatest authority. He operated on 360 patients. Of these, one died of infection, one from chloroform, one from gangrene from too vigorous manipulation made elsewhere and two from causes not given—five in all. There were four recurrences. Kovacs[7] had 232 cases with one death from imperfect technic. In 144 cases traced there was one recurrence. Castenholz[5] advises operation in all cases, because it is the only means of cure and because by curing the trouble in childhood when time is worth but little, the patient is spared incapacitation in later years when the struggle for existence is on. Pfaehler[11] advises operation in all cases. He had one recurrence and no deaths in forty-six cases. He treats them as ambulants, the patient being brought to the hospital only for operation and returned home immediately afterward.

More conservative are Coley and Bull,[12] who, after an experience of 1,500 cases, advise operation after truss treatment of one or two years. Earlier operation is done if there are frequent strangulations, if the hernia is irreducible or complicated with hydrocele. In femoral hernias operation is always done. Buford[13] likewise does not operate before the fourth year, except in emergencies. Maass[14] is likewise disposed to be conservative because of the dangers of the operation. He operates only when the hernia increases in size, when there is troublesome eczema or when the parents are unable to care properly for the child. The reason for this conservatism is the danger of chloroform and the danger of injuring the vas and the vessels of the cord with subsequent necrosis of the testicle. Coley agrees with Maass that the operation is more difficult than in adults.

[14] Maass: Deutsch. med. Wchnschr., 1901, xxvii, 148.

The point of view of those who operate is, therefore, largely influenced by results achieved. Those who advocate operation must answer both for deaths and for failures, and these factors are both still large enough to dampen enthusiasm. Hernia in children rarely causes death and it devolves on the advocates of operation to show a mortality less than that of the untreated cases. Statistics are not sufficient to determine the point. Stiles[10] estimates that 7 per cent. of all children visiting the clinic (Polyclinic at Edinburgh) have hernias. His mortality was nearly 1.5 per cent. Castenholz[5] estimates the mortality at 0.3 per cent. Those who can show a mortality so low as this are justified in advocating operation, without reserve.

That operation *per se* is without danger is evident, and it is only the surgical accidents that make us pause. Thrombosis after operation has not been observed. Death from chloroform, so often complained of by the Germans, can be avoided by giving ether. Lung complications and intestinal disorders may appear merely coincident with, or because of, the operation; it is impossible often to say which. Injury to the vas and cord is purely a technical error and should not occur, at least not more than once. The surgeon's obligations resolve themselves into a question of asepsis. The delicate skin does not admit of rigorous cleansing and the difficulty of sterilizing a urine-soaked skin is considerable. The greatest difficulty, however, is in keeping the wound clean after operation. Collodion dressing is often inefficient to protect the region. It is this difficulty in keeping the parts clean that has caused many operators to prefer to wait until the child has reached an age when it can cooperate in the matter of cleanliness. After the child has attained the age of 3 or 4 years, spontaneous cure or disappearance for any considerable time is unlikely After this time the child is more likely to be conscious of his handicap, and the desirability of a permanent cure is proportionate to the degree of discomfort and the sensibility of the child. The operation is entirely safe and the cure nearly certain.

The type of operation likewise is subject to differences of opinion. If the patent canal is the only factor, those who advise a simple ligation of the sac are right. Castenholz closes the canal only when it is wide. Stiles believes that the Bassini technic is not needed, because of the shortness of the canal. Coley's experience is in favor of the regular Bassini.

Ambulant treatment is readily applicable and places the operation within reach of many who could not otherwise avail themselves of it. Castenholz sees his patients only after a week or ten days when it is desired to remove the stitches. This shows a confidence in the integrity of the dressings which is not warranted by the experience of most operators; but if the dressings can be observed from time to time Castenholz' method is a very efficient one. My own experience has been that the ambulant treatment is more satisfactory in children after four years than in infants. In the latter, no matter how careful the dressing, trained supervision is required.

## SUMMARY

1. All inguinal hernias in infants are due to persistence of the processus vaginalis.

2. Inguinal hernias are not cured by the truss and rarely recover spontaneously.

3. Surgery is permissible in all cases if the facilities are of the best and the operator is skilful. Operation is urgent if the hernia protrudes persistently or if the child is annoyed greatly by retentive appliances which lessen his activities or produce excoriations. Operation is demanded if the hernia is irreducible or strangulated.

4. Because of the difficulty of maintaining an aseptic field after operation it is wise conservatism to wait until the child has reached such an age as will enable him to lend his cooperation, that is, until about the fourth year.

5. Palliation is demanded when organic disease is present or adequate facilities for operation are not at hand.

Rialto Building.

## ABSTRACT OF DISCUSSION

**Dr. Coleman G. Buford**, Chicago: The treatment of hernia of infancy is nearly always considered and discussed with that of children in general and consequently there is great confusion. Hernia in infants is one thing, while that in older children is another. I shall try to limit my remarks to the former.

I admit that a large number of cases are *congenital*; but I have been surprised at the large percentage of supposedly congenital cases showing anatomic evidences of being acquired hernia.

The question of whether or not to operate on uncomplicated inguinal hernia in infants was definitely settled in America by the writings of Bull and Coley, based on almost unparalleled experience and statistics. Their conclusion was that children under 4 years of age should not be operated on for uncomplicated inguinal hernia until truss treatment had been used intelligently for four years. We have endeavored to follow this rule in my service at the Children's Memorial Hospital; but in older children we are inclined to shorten the period of truss treatment.

Babies should not be operated on as a routine because of their susceptibility to infectious diseases when brought among other sick children; diphtheria, scarlet fever, measles and erysipelas appear too often when least expected. Again, male babies are especially liable to wound infection when herniotomized, because of the wound's close proximity to the genitals and anus. Babies are susceptible to the damages of pyogenic infection; even stitch-hole abscesses may easily be the indirect cause of the death of an infant.

I usually refuse to operate on children until (1) they are of such an age and state of intelligence as to aid in keeping their dressings and bedding clean; (2) a complication not easily corrected arises, such as strangulation or existence of an incarceration; (3) failure to retain the hernia by a correctly fitting truss occurs; (4) parental neglect persists, and (5) parents insist on the operation.

We do the Bassini operation on all infants, using one and never more than two sutures to close the posterior wall, catgut closure for the external oblique and horsehair for the skin. Our skin incisions rarely exceed 1¼ inches.

How shall we dress these? Not with a fluff and spica; but with a thin pad of gauze, the length of the wound, over which we place a gutta-percha covering which is sealed to the skin by collodion. After drying, in male babies, we use an apron or watershed of the same material, sealed to the pubes and dropped over the penis, so that the urine is diverted from the wound. Covers must not rest on the dressing. Infants are put in the regular hospital bed, which is surrounded and covered by one or more layers of sheeting, dropped to the floor, thus cutting off the under draft of air. The bed may be heated with hot-water bags hung as radiators. The child wears stockings and a shirt which does not extend below the navel, thus avoiding wetting and contact with the dressing.

The patients not operated on are treated by the use of trusses. Our results are satisfactory and there are few returns. We use the cross-body truss for all single and Hood's truss for double hernias. The material should be hard rubber, the strap excepted. When straps are wet they should be changed. The truss should be washed and dried once or twice daily and oftener if soiled; it will then give off no odors. The skin should be kept hard by hand friction and dusting powder. The truss must be worn day and night for curative purposes. It must fit properly; fit it yourself. It must not make pressure or cause friction sores; it must retain the hernia under all conditions.

# THE HOSPITAL MANAGEMENT OF CONTAGIOUS DISEASES *

D. L. RICHARDSON, M.D.
Superintendent Providence City Hospital
PROVIDENCE, R. I.

It has long been believed, and still is, that the so-called "contagious diseases," comprising such diseases as scarlet fever, diphtheria, whooping-cough, measles, small-pox, chicken-pox, mumps and rubella, are to a large extent contracted by aerial transmission. Much evidence against this view has accumulated during the last few years and one purpose of this paper is to discuss this evidence.

It is only the practical experience of the hospitals of England and France and the Providence City Hospital that will be presented to show the importance of contact infection and the relatively small factor, if any, of aerial transmission. The paper is not based on laboratory findings.

The French were the first to doubt the theory of air-borne disease and the importance of controlling contact infection. To Grancher of Paris belongs the credit of being one of the first to put these ideas into practice. He isolated contagious diseases in the wards of a general hospital. Wire screens were placed about the beds to indicate that certain precautions were to be taken in handling these patients. These precautions were based on the method of strict asepsis. From 1890 to 1900, among the 6,451 patients admitted to Grancher's wards, diphtheria was introduced forty-three times and only once did the disease develop in the ward; scarlet fever was introduced nineteen times and seven cases developed. Less success was obtained with measles, although infections were reduced two-thirds. The evidence was, however, conclusive enough to convince Dr. Grancher that even measles was not spread by air.

Out of this simple but important beginning have developed various methods of construction for segregating the various diseases. Aseptic nursing is employed, whatever the type of separation. Some disregard air separation; others aim to interrupt, partially or wholly, air exchange between compartments occupied by patients. All plan to establish physical separation and to prevent contact. Out of Grancher's method developed the barrier system which is largely used in England. This is the method of isolating patients in a common ward. The beds are generally placed on centers 12 feet apart. In the beginning, the beds were surrounded by sheets kept wet with bichlorid of mercury. At present the wet sheets have been dispensed with and the bed is marked in some way. In one hospital, two uprights are set on the floor, one on each side of the foot of the bed, and a cord of colored tape is stretched between. This serves merely to indicate to nurses that precautions are to be taken.

Another method is the so-called cubicle system. The cubicles are small rooms with partitions more or less complete. In many instances the partitions are about 7 feet high. They are of silicon-plaster, glass, or a combination of the two. The rooms are arranged either on one side or on both sides of a common corridor, or sometimes in England, old wards have been cut up into separate compartments by partitions which do not reach the ceiling, all compartments being ventilated from the common air-space above. The cellular block system consists of rooms back to back with glass partitions; access to the rooms is from verandas.

Permit me to report some of the results in English hospitals where medical asepsis has been tried since 1907. In the Plaistow Hospital, Dr. Biernacki has been using the barrier system extensively, as well as the cellular block system. Dr. Biernacki writes that he would isolate the following diseases with the barrier system:

1. Diphtheria.
2. Whooping-cough.
3. Mumps.
4. Rubella.
5. Typhoid fever.
6. Septic infections.
7. Ringworm, except when not additional to scarlet fever.

He does not attempt to isolate measles or chicken-pox, and hesitates to do so with scarlet fever. In his cellular block system all of the before-mentioned diseases are treated as well as typhus. In the block there has been no cross-infection for three years. He quotes no statistics relative to his barrier work, as he has not reached a final decision as yet.

Dr. F. Foord Caiger, medical superintendent of the South-Western Hospital, London, reports on eighteen months from Jan. 1, 1907, to June 30, 1908, on the cubicle system. The partitions are 7 feet high, the lower half being granite silicon-plaster and the upper half glass in a metal frame. Seven hundred and four patients were placed in these cubicles, of whom 289 were scarlet fever convalescents who were placed in them two days and nights before their discharge. The remaining 415 were isolated in them for the following reasons:

1. The original diagnosis was uncertain.
2. The disease, though recognized, was one that called for separate isolation.
3. The patient had been exposed to another disease prior to admission and therefore was possibly incubating a second disease.
4. The patient was suffering from more than one infectious disease.
5. The disease was obviously of a non-infectious nature.

In addition to the 289 convalescent scarlet fever cases referred to above, the following diseases were placed in cubicles:

Scarlet fever, 163 cases, in the eruptive stage of the disease.
Rubella, 82 cases.
Measles, 22 cases.
Diphtheria, 31 cases.
Whooping-cough, 17 cases.

Of these 704 patients, twenty developed a second disease in the cubicles. Three of this number, however, were incubating the disease on admission and a fourth was infected by a ward maid who was suffering from diphtheria. Of the sixteen diseases arising in the cubicles,

---

* Read in the Section on Diseases of Children of the American [illegible] at the Sixty-Fourth Annual Session, held at [illegible] 1913.

six were scarlet fever, six were chicken-pox, two were rubella, and two were measles. In two instances, one chicken-pox and one measles, there had been no recognized case of the same disease previously in the ward for a period of six weeks and two months respectively. Thus only fourteen persons apparently contracted another disease from patients in the cubicles. It will be seen that no case of whooping-cough or diphtheria developed. Dr. Caiger concludes that of all the before-mentioned diseases, chicken-pox is the only one which he has ceased to put into cubicles because of the six cases arising in the first six months of the period reported on. In his 1911 report he speaks as follows:

> The incidence of secondary infectious disease among the 269 patients treated in cubicle wards was 1.8 per cent., whereas in general wards it was 7.6 per cent. In addition to these 269 patients, chicken-pox and measles being the only excluded, 177 scarlet fever convalescents were placed in one of the cubicle wards for the last two days and nights of their stay in the hospital. In all, 2,547 patients have passed through the cubicles during the five years they have been in use. As an extension of isolation provision they have proved of the utmost service.

Dr. Thompson of the North-Eastern Hospital, London, reports on an experience of two years with the cubicle and box-room system. To the cubicles, 1,290 patients were admitted. The following cross infections have developed:

| | Cases | | Cases |
|---|---|---|---|
| Scarlet fever | 5 | Whooping-cough | 1 |
| Rubella | 3 | Chicken-pox | 3 |
| Measles | 2 | Diphtheria | 2 |

His conclusions are rather conservative. During the last twelve months, he placed in the cubicles doubtful cases of scarlet fever and diphtheria and is averse to placing other infectious diseases in them.

To the box-rooms, 660 patients were admitted, suffering from the various infectious diseases except chicken-pox. The following cross-infections developed:

| | Cases |
|---|---|
| Scarlet fever | 6 |
| Rubella | 3 |
| Measles | 2 |
| Whooping-cough | 1 |
| Chicken-pox | 3 |

In his 1910 report, Dr. Goodall, medical superintendent of the Eastern Hospital, London, describes the conversion of a long ward, 106 by 28 feet, into twenty cubicles with glazed partitions. Ten rooms open from both sides on a common corridor. These cubicles were opened for patients Sept. 6, 1910. Up to March 25, 1911, 142 patients passed through this ward. Of these, 110 suffered from an infectious disease, while thirty-two did not. The following diseases were included:

| | Cases | | Cases |
|---|---|---|---|
| Scarlet fever | 16 | and measles and chicken-pox | 1 |
| and diphtheria | 2 | and measles and rubella | 1 |
| and measles | 5 | Measles | 25 |
| and chicken-pox | 9 | and chicken-pox | 1 |
| and rubella | 2 | and rubella | 1 |
| and whooping-cough | 1 | Chicken-pox | 3 |
| and diphtheria and measles | 1 | Rubella | 13 |
| and chicken-pox and scabies | 1 | Mumps | 1 |
| Diphtheria | 5 | Erysipelas | 1 |
| and measles | 5 | Influenza | 1 |
| and chicken-pox | 3 | Enteric fever | 1 |
| and rubella | 1 | Lobar pneumonia | 4 |
| and whooping-cough | 2 | Scabies | 1 |
| and mumps | 2 | Diseases non-infectious | 32 |
| | | Total | 142 |

Patients were not selected as to the stage of the disease or as to position in the ward. One child contracted chicken-pox during the six months' period.

Dr. C. Rundle of the City Hospital, Liverpool, reports that during 1910 and 1911, 668 cases were treated by the barrier system. These cases included all contagious diseases, not excepting measles and chicken-pox. During these two years, only two patients developed a secondary disease, both contracting scarlet fever. Other hospitals in England which are employing aseptic nursing are situated at Manchester and Walthamstow.

The earliest and parent hospital, the Pasteur in Paris, is perhaps one of the most successful. Small-pox is admitted to this hospital, which is done in no other hospital so far as I am aware. I know of only one small-pox cross-infection. Two other Paris hospitals, the Herold and the Hôpital des Enfants Malades, employ aseptic methods, but I do not know their results.

I shall now offer for consideration an experience in the Providence City Hospital of three years, from March 1, 1910, to March 1, 1913, with aseptic nursing of infectious diseases. The special construction of this hospital and introduction of aseptic nursing in this country is the work of Dr. Charles V. Chapin, superintendent of health of the city of Providence.

Patients are accommodated in three two-story buildings' situated parallel, one each for diphtheria and scarlet fever, and one an isolation building, so-called, for all other infectious and mixed cases. Each floor of the diphtheria and scarlet fever buildings is divided into a ward of twelve beds and seven or eight rooms arranged on either side of a central corridor. The side rooms vary in size, containing from one to three beds. The ground floor has also an admitting room, connecting with a doctors' gown and wash room, and a patients' bath. The large number of small rooms furnishes the opportunity for isolating mixed or doubtful cases and for detaining new cases a certain period of time before they are allowed with convalescents. Each serving kitchen is provided with a utensil sterilizer for sterilizing dishes, etc.

Each of the rooms, except the large ward, is provided with a lavatory with forearm levers and without plugs, hooks for gowns, a bar on which to hang individual towels and a small shelf for the patient's thermometer, etc. The usual nursing utensils are kept on a bedside table. All the paint has an enamel finish so that it can be easily washed.

On the first floor of the isolation building are twelve single rooms arranged on either side of a central corridor. Ten of them are arranged directly opposite so that the doors open opposite to each other. Beside each door and opening into the same room, is a full-sized window which permits of better observation of patients by the nurses and keeps the patients better contented by permitting them to see their neighbors across the hall. The partitions rise to the ceiling and are of studding, lathing and plaster. Each room is furnished the same as those just described. This floor also has its serving kitchen, toilet, bath and operating-room. In the serving kitchen is a large utensil sterilizer for sterilizing dishes, medicine glasses, etc., which come from the patients.

The construction of the second floor of the isolation building is similar except that the rooms contain from one to three beds, making it possible to accommodate in the same room several patients isolated for the same purpose. The doors to all the rooms in the building are always left open unless there is some unusual reason for closing them.

The dormitory for nurses is in the administration building; that for female help is in the service building and for male help over the power house and laundry.

The administration of the hospital has been worked out along the line of avoiding contact infection. It has been our aim to avoid cross-infection and infection of employees by strict asepsis. Every new nurse and employee who has to go into the wards is thoroughly impressed with the idea that if he gets sick it is most likely his own fault and probably due to putting his fingers or something else contaminated in the ward into his mouth; employees understand that if any cross-infection develops they are liable to investigation as to the care they exercise in their work. Every employee has a culture taken on beginning work and before going into the wards. Everyone must be vaccinated before or soon after entering on his work. No prophylactic antitoxin is administered either to employees or to patients.

I shall not attempt to present all the details of our technic, but shall outline the more important; first, those relating to the general administration, and second, the more direct care of the patient.

The resident physicians have their quarters in the administration building and all eat in the same dining-room. While working in the wards, white duck suits are worn, and in each ward a gown is put on if it is necessary to make examinations and thus come in contact with the bedding and patients. On leaving the ward, the gown is removed in the gown- and wash-room and the hands are carefully washed with soap, water and brush in the special basin to which I have already referred. Great care is exercised when not wearing a gown to avoid allowing any part of the clothing to touch the bed, bedding or anything else. Physicians wear the usual hospital uniform and in addition a short-sleeved jacket to avoid sleeve infection.

The nurses all sleep in the same home and eat in the same dining-room. When off duty, they are allowed to leave the hospital as freely as from any general hospital. When the nurse goes on duty, she goes to the dressing-room for that ward where she has two metal lockers, one for clean clothes and one for infected clothing. She puts on her ward clothes and goes to the ward. She changes her dress, cap, apron and bib only. When going off duty, she removes her infected clothing first, washes hands and face, and then puts on her uninfected uniform. The sleeves of the uniforms are either short or rolled up.

The maids and other help put on gowns when entering the wards. These gowns have short sleeves so that the sleeves will not be contaminated. Otherwise employees observe the same care as do the nurses. The ward help eat in the same dining-room and sleep in the same quarters with all the other help, and they, too, are free to come and go when off duty. It is insisted that every case of illness among nurses and help be reported at once in order that no mild infection may be overlooked.

The same kitchen furnishes food to patients and employees. Food supplies are sent to ward kitchens in paper bags and paper trays, and these are destroyed. Such dishes as must pass between kitchens are boiled before leaving the ward and washed again in the main kitchen.

All hospital linen is washed in one laundry, the washing being done in ordinary washers.

The greatest source of infection is certainly the patient himself. If we are to minimize diseases arising in the hospital, we must have very careful regulations and insist on their obedience. Our method of procedure has been based on the contact infection idea and we have disregarded air transmission unless one chooses to insist that the coughing of a patient directly into one's face is air-borne infection.

I will trace briefly the method of care from the time the ambulance goes to the house until the patient is ready to walk out of the hospital. The various infectious diseases, including tuberculosis, are brought to the hospital in the same ambulance or in a coupé. There is nothing peculiar about the construction of these vehicles, except that the interior can be freely washed with soap and water without damage. The attendant and the driver wear clean, washable coats on every ambulance trip. Careful inquiry is made as to the presence of other recent previous infection of the patient or of any one in the house. The patient is wrapped in blankets and brought to the hospital, where he is placed in the appropriate admitting-room. The driver and the attendant return to the stable, remove their coats and wash their hands. The infected blankets and coats are put in a hamper and later sent to the laundry. The interior of the coupé or ambulance which has come in contact with the patient is washed with soap and water.

The patient remains in the admitting-room until the admitting officer has made a physical examination. A culture nose and throat and vaginal smear are taken before admitting to the ward. Even though it may be an uncomplicated case belonging in that ward, every new patient is held in detention from five to seven days, and often longer. "Detention" means that the patient is placed in one of the rooms off the ward used for the purpose where aseptic precautions are observed. Should there be any doubt at all about the diagnosis, or exposure to or suffering from mixed infections, the patient is sent to the isolation building, or else is barriered by placing a red card on the bed.

Briefly, our technic in the care of detention and barriered case is as follows: The patients may occupy single rooms off the ward or be in detention separately or collectively in larger rooms. They are kept in bed and are not allowed toys or anything else which can be thrown from bed to bed. The hands of doctors and nurses are washed after treating the patient. Each patient is supplied with a thermometer, basin, pus-basin, bed-basin, bed-pan, etc., which are kept on a table beside the bed. There is a gown to be used when coming in direct contact with the patient. All dishes are boiled after using. Our object is to control in-going and out-going infection to or from new cases.

The construction of the isolation wards has been referred to. The furniture is small in amount, and, like all the ward furniture, easily cleaned. The isolation wards have proved the most valuable section of the hospital. In them we have not hesitated to treat any of the so-called contagious diseases, except small-pox, in any stage, as well as cases for observation only. We are obliged to treat cases of measles, chicken-pox, whooping-cough, rubella, mumps, etc., and it has been very convenient and, we believe, safe to use these single rooms, equipped as they are. It saves opening a large ward and furnishing a separate supply of nurses and maids for each.

We confine the infection to the rooms immediately occupied by patients. We believe that the corridors, serving kitchen, linen-room, bath and toilet are as safe and free from infection as those of any general hospital. The same nurses care for the patients on a single floor. The nurse washes her hands with bar soap in running water, using a brush, and dries them on an individual towel every time she touches the patient or anything in the room. After handling measles and chicken-pox, in addition to the washing, a one-minute immersion in an antiseptic solution is required. If the nurse comes in close contact with the patient she puts on a gown. Each patient is supplied with everything as described above. All dishes and nursing utensils coming from these patients are put directly into a sterilizer, if steam can be used, or 1:20 phenol (carbolic acid) solution is used for rubber and glass goods. Bed-pans and urinals are emptied into a hopper and put into a tub of 1:20 phenol solution, in which they are kept an hour or more before removal to the warming rack.

Small children who would play on the floor are kept in bed throughout their hospital residence. Larger children or adults are allowed up, but confined to their rooms, except when they are allowed outdoors, when they are also kept apart. The doors of the rooms stand open all the time, and this practice, together with the extra corridor window, allows patients to see each other and to talk back and forth, and they seem very contented.

When a patient is discharged, the linen in his room is sent to the laundry, the mattress and pillows to the steam sterilizer, and nursing utensils are sterilized. The bed, wash-basin, table, chair, floor and walls within easy reach are simply washed with soap and water. Preferably the room is aired for twenty-four hours, but if we need it we have not hesitated to put a new patient into it immediately. Rooms are never fumigated.

Every discharged patient receives a thorough soap and water bath including a shampoo. The clothing has been sterilized by steam, 10 pounds for thirty minutes, so far as possible. Those articles which steam would injure are treated with formaldehyd vapor in the same chamber, to which 1 or 2 pounds of steam has been added.

It will be noticed that we do not use any disinfectant solution for the hands, except after measles and chicken-pox. It has seemed to us that to wash the hands with soap and water and brush every time they became infected, if we could make it convenient, would be sufficient. There is no antiseptic solution which is efficient under immersion of less than one minute. An antiseptic solution is not necessary after washing, except perhaps in the case of measles and chicken-pox.

Time will not permit me to present the results of aseptic nursing after three years' experience in such detail as I should like to. I believe that the Providence City Hospital is the only hospital in this country which keeps an accurate record of all diseases contracted in the hospital by patients and help, and publishes it in annual reports. I sincerely wish that it were a general practice so that we might have facts on which to base comparisons of the results.

I shall first mention briefly the number of diseases contracted in the hospital, with incidence of infection, among help, scarlet fever patients and diphtheria patients; then take up in more detail the results of treatment in our isolation wards, which is the real test of aseptic nursing.

Among the seventeen physicians who have worked in the wards, the only disease contracted was diphtheria, three cases, 18 per cent. Among forty-seven graduate nurses, scarlet fever developed once, 2 per cent; diphtheria twice, 4 + per cent; rubella once, 2 per cent. Among 183 pupil nurses who work in the wards two months, scarlet fever occurred eleven times, 6 per cent.; diphtheria ten times, 5.4 per cent.; rubella once, 0.5 per cent. Among eleven nurse maids, no disease occurred. Among eighteen ward kitchen maids, one developed scarlet fever, 5.5 per cent., and one diphtheria, 5.5 per cent. One laundry maid developed scarlet fever and a night telephone operator diphtheria.

Diseases contracted among the 861 patients who have been admitted to the diphtheria ward are as follows:

| | | | |
|---|---|---|---|
| Scarlet fever | 2 | Rubella | 3 |
| Diphtheria | 1 | Whooping-cough | 3 |
| Chicken-pox | 18 | Total | 27 |

This constitutes an incidence of secondary infection of 3.1 per cent.

Diseases contracted among the 649 patients who have been admitted to the scarlet fever ward are as follows:

| | | | |
|---|---|---|---|
| Diphtheria | 3 | Chicken-pox | 13 |
| Measles | 4 | | |
| Rubella | 1 | Total | 21 |

This constitutes an incidence of secondary infection of 3.2 per cent.

The diseases contracted among the patients in the isolation building have been confined to measles, chicken-pox and scarlet fever. Between March 1, 1910, and March 1, 1913, the period which this paper covers, there have been treated in this ward 842 patients. Of this number, 151 were there less than a week, and 691 more than a week. These 842 patients suffered from the following diseases:

| | | | |
|---|---|---|---|
| Chicken-pox | 76 | Tonsillitis | 22 |
| Diphtheria | 137 | Tuberculosis pulmonary | 16 |
| Diphtheria carrier | 138 | Vaginitis gonorrheal | 8 |
| Erysipelas | 3 | Variola | 2 |
| Influenza | 1 | Vincent's angina | 4 |
| Measles | 242 | Whooping-cough | 128 |
| Mumps | 11 | Tinea tonsurans | 1 |
| Noma | 6 | | |
| Ophthalmia gonorrheal | 2 | | 1,066 |
| Rubella | 37 | Non-infectious diseases | 88 |
| Scarlet fever | 231 | | |
| Syphilis | 1 | Total | 1,154 |

The excess of diseases over the number of patients is accounted for by mixed cases.

The following diseases have been contracted: chicken-pox, 8 cases; measles, 25 cases; scarlet fever, 10 cases; a total of forty-three cases and an incidence of 5 per cent. Remember that the foregoing diseases were placed in the isolation rooms in any and all stages.

So far as I know no other hospital, except the Pasteur, has ever undertaken to care for such a variety of diseases by aseptic nursing. It is fair to conclude that the following diseases can safely be treated by the cubicle system: diphtheria, scarlet fever, whooping-cough, rubella, mumps, gonorrheal infections. There may be some question with relation to chicken-pox and measles. I believe that when our technic is better perfected, these also can be recommended as amenable to aseptic nursing. I believe that the cross-infections were due to faulty technic. The cross-infections have appeared mostly in outbreaks and we have had intervals as long as fifteen months in the isolation wards without a secondary disease arising.

## ABSTRACT OF DISCUSSION

DR. H. E. ROBERTSON, Minneapolis: Does Dr. Richardson place pupil-nurses in his isolation ward, or does he use trained nurses for this strict aseptic work?

DR. D. L. RICHARDSON, Providence, R. I.: For the first eighteen months of our work in this isolation ward we used pupils, but after one or two experiences we felt that it was not safe. If we had pupils for six months or a year we should deem it feasible, but we have them for only two months. It is not long enough to trust them to nurse cases of measles and chicken-pox and possibly scarlet fever. If they are in the ward for several months' preliminary training then they can be trusted. Our object is to develop an aseptic technic. The nurse is under strict supervision for a certain period of time because we must have faithful assistants. The work in fact depends entirely on the nurses. They are the ones who care for the patients, and it is necessary to enlist the cooperation of every one in the hospital to insure success. I am glad to say that in our work every one has imbibed the spirit of aseptic nursing and does not fear the diseases in any way, being careful to avoid any opportunity of contact.

---

# HOLLOW FOOT—PES CAVUS *

CHARLES A. PARKER, M.D.
CHICAGO

An increase in the concavity of the longitudinal arch of the foot is of frequent occurrence. In some persons it is entirely normal and causes no symptoms whatsoever. It may, however, become so great as to constitute a real deformity, and in severer cases be quite as disabling and painful as the worst flat-foot. Like flat-foot, its development is usually insidious and may be due to several different causes. The essential feature is the increased concavity of the arch with a shortening of the structures of the sole. Dorsal retraction of the toes is usually present and bears an important relation to its development, but is not a part of the cavus itself. It is usually associated with some malposition of the foot, as varus or valgus, equinus or calcaneus. It is more frequently associated with equinus or equinovarus. So-called true or essential cavus is rare. The deformity may be fixed or reducible.

In the earlier cases the normal contour of the foot can usually be restored by simple manipulations, but in the fixed cases changes in the bones and soft parts make this quite impossible by any such simple measures. So in the treatment, milder measures are commonly sufficient in the earlier cases, while in the fixed condition operations on the bones and soft parts are frequently necessary to restore in a measure the normal condition of the foot.

Such is a brief outline of the condition with which we are all familiar. We are not, however, so familiar with the etiology and development of this affection. It was this obscurity surrounding the origin and development of several cases under our care that first suggested to me an attempt at a better understanding of the whole subject of cavus. Several lines of investigation were considered but it was early seen that a thorough knowledge of the mechanism of the deformity was an essential factor in them all. Thus my study was naturally directed to this phase of the subject which I finally determined to make the dominant part of my paper after realizing the futility of attempting to present at this time a complete survey of so large a subject. While this determination leaves much to be desired in the way of unraveling questions of obscure etiology, etc., it has to commend it the virtue of directness and concentration of effort on one essential at a time. General principles of prophylaxis and treatment will be referred to and etiology will be incidentally discussed.

## THE MECHANISM OF CAVUS

The essential deformity of cavus is limited to the region of the tarsus and metatarsus. The long rigid metatarsals, with the slightly movable cuneiforms, the scaphoid and the cuboid, form the front part of the arch, while the astragalus and os calcis form the back part. Between these two portions is the mid-tarsal joint where the greatest amount of flexion takes place. Rotation around a shifting oblique anteroposterior axis passing through the navicular, the head of the astragalus and the posterior part of the calcaneo-astragaloid articulation adds a varus or a valgus position to the foot. The concavity of the arch is normally maintained by the shape and arrangement of the bones, the ligaments, muscles and fascia of the sole and the muscles of the dorsum of the foot. The bones, ligaments and fascia are passive in their function and depend on the active muscles to maintain their proper relations and tone. The rigidity of the bones preserves the general form of the foot in paralysis of the muscles, but the ligaments and fascia only imperfectly perform their functions in this condition. The muscles are the prime factors in maintaining and increasing the arch, and disturbance of their function is responsible for the development of most of its deformities.

Thus the muscles in the sole of the foot, including the long flexors passing to the toes, tend to increase the concavity while those attached to the dorsum of the foot both in front and behind the ankle exert their influence in the opposite direction.

The strongest extensor of the arch is the Achilles tendon acting on the posterior part. Paralysis of its muscle is a common cause of cavus, the so-called paralytic type accompanying calcaneus. The mechanism is very simple here and needs no further discussion. This is the only arch extensor behind the ankle and so is the only muscle in this region whose weakness can give rise to cavus. If the other muscles of the foot are also paralyzed, of course, cavus may not develop.

The conditions in front of the ankle are more complicated. Here the tibialis anticus is the chief opponent of the gastrocnemius and soleus, and a strong extensor of the arch. It is aided by the peroneus tertius and the long and short extensors of the toes.

The extensors of the toes are weaker than the tibialis and act only indirectly on the arch. This indirect action, however, is exerted in conjunction with the flexors of the toes and is of the utmost importance in controlling the stability of the arch.

So fundamentally important is this interrelation of the flexors and extensors of the toes in preserving the normal condition of the arch that, if we leave out of account the paralytic calcaneus and possibly the congenital types, I believe it is safe to say that a perversion of the normal reciprocal action between the flexors and extensors of the toes can account for most, if not all, of the remaining types of cavus. Of course perversion is an extremely elastic term, yet this general conclusion, if true, by narrowing the field of endeavor offers a distinct advance in the approach to a solution of this obscure problem and incidentally a justification for this paper.

I shall attempt to substantiate this conclusion and make clear the character of the interaction.

A careful study of the normal interaction of these muscles will best lead to an appreciation of their action under abnormal conditions.

In the normal foot with properly balanced muscles the toes lie extended directly in front of the heads of the

---

* Read in the Section on Orthopedic Surgery of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

metatarsal bones with neither dorsal nor plantar deviation. This is the position of rest in which the muscles most easily maintain their balance. The foot is usually at right angles with the leg or slightly extended. Active flexion or extension of the toes immediately affects the flexible arch, and in this manner: dorsal extension increases the concavity, and plantar flexion decreases it. This can easily be determined by trying it on a normal foot. Neither group of muscles acts directly on the bones of the arch; their action on the toes is responsible for the change. This change of the arch is explained as follows: The centers of rotation in the metatarsophalangeal articulations are near the centers of the heads of the several metatarsal bones. The tendons pass respectively dorsal and plantar to these centers to their attachments to the phalanges and maintain the arch in its normal or resting position, when the toes are straight ahead; but let the toes be actively or passively extended, the flexor tendons on the under side necessarily must be pulled upward over the rounded heads of the metatarsal bones to allow the toes to take their new dorsal position. In other words, more of the flexor tendon is distal to the head of the metatarsal than was the case at the beginning. In order for this to occur the flexor tendon must stretch an equal amount or else the span of the arch must be just so much diminished; that is, if ½ inch of a flexor tendon is drawn up in front of a metatarsal bone, it means that the muscle from which it came stretched ½ inch or that the chord of the arc which it originally spanned was shortened ½ inch. Of course the tendon itself does not stretch although the muscle may relax. Either one or both of these two things, relaxation of the muscle or shortening of the chord of the arc, must always occur to allow dorsal extension of the toes. It is probable that normally both occur. If the tendons were fixed cords, the second method, by shortening the arch, would be the only possible one. Two sets of flexor tendons are concerned in this action, the long flexors passing behind the ankle and the short flexors lying entirely in the sole. The function of the latter is not affected by movements at the ankle, while the function of the long flexors is somewhat affected by its movements. When the foot is extended they are slightly relaxed and when it is dorsally flexed their tension is somewhat increased. This relaxation of the long flexor tendons in extension of the foot tends to weaken their effect in the previously mentioned interaction. This tendency, however, is slight as they pass so near the axis of motion at the ankle that flexion or extension of the ankle makes very little difference in their ultimate action. As they are much the stronger flexors of the toes this slight loss in foot extension probably still leaves them the most effective flexors of the toes. On the other hand, the dorsal extensors of the toes pass a greater distance in front of the axis of motion at the ankle and are markedly increased in their capacity to extend the toes by strong extension of the foot and thus gain definite power over the flexors that easily maintained their balance in the normal or resting position of the foot. Much that has been presented to amplify the simple observation that dorsal extension of the toes increases the concavity of the plantar arch can be used with equal effectiveness in showing the converse to be true, that plantar flexion of the toes decreases the concavity of the arch.

While I am at present especially concerned with the production of cavus, a brief consideration of the manner in which a decrease in the concavity of the arch is produced will be of distinct value in emphasizing the force of the original statement regarding the fundamental importance of the interaction of the flexor and extensor tendons of the toes in health and disease.

In active or passive plantar flexion of the toes the dorsal tendons are drawn beyond the heads of the metatarsals. This necessitates a lengthening of the dorsal tendons or a dorsal movement to an equal degree of the distal end of the arch.

The dorsal muscles may relax and thus allow some of the lengthening, yet they must be kept fairly active to maintain the position of the foot against the extending force of the plantar flexors. This disturbs the equilibrium of the resting position and throws an increased extending force on the front of the arch that is not present during rest. It is probable that relaxation of the extensor muscles and dorsal movement of the distal end of the arch occur together under mormal conditions. If the dorsal tendons were fixed cords dorsal movement only would take place. Dorsal movement of the front of the arch can take place in just one other way and that is by extending the muscles of the calf allowing dorsal flexion at the ankle. The large size of these muscles, however, and their habitual synergic action with the flexors of the toes practically exclude this as a normal method of compensation. The short dorsal extensor would not be affected by the ankle movements.

In health the various changes in the arch are purely physiologic and the normal resting position of the foot is readily resumed, but under pathologic conditions this position either cannot actively be assumed or if assumed cannot be normally maintained.

Applying these principles in certain pathologic conditions we shall now see how well adapted they are to explain the changes that initiate cavus.

The disturbed action of the flexors and extensors is usually secondary in nature, the real affection being in the synergic muscles. Thus the originally affected muscles primarily destroy the balance of the foot and the perfectly physiologic action of the flexors and extensors under the changed conditions produce the deformity.

Usually back of the muscular affection is the nervous lesion, primary muscular dystrophy as a cause being a rare possibility and quite outside of my experience.

As a simple and instructive illustration let us take the familiar anterior tibial paralysis of acute poliomyelitis. First, there is a foot-drop due to the unopposed action of the muscles behind the ankle. With the foot-drop there is overextension of the toes and in strict accordance with the law of interaction of the flexor and extensors of the toes an increase in the concavity of the arch. At first raising up the ball of the foot completely restores the arch and corrects all deformity. Later, however, contractures of the muscles behind the ankle, changes in the muscles, fascia and bones of the foot make complete restoration in this manner impossible.

This is a very common form of cavus and is usually associated with varus or valgus. When the posterior tibial and possibly other muscles behind the internal malleolus are weakened valgus develops usually with a diminished equinus, lessened dorsal retraction of the toes and a loss of the cavus action. Cavus may not develop at all if the extensors of the toes are also paralyzed or if both flexors and extensors are paralyzed, as in extreme cases. Going from this flagrant example through the gamut of mild and insidious attacks of this and other affections on the innervation of the tibialis anticus, it is readily seen how difficult it may be in a given case to determine the etiology or the primary seat of the affection. With all muscles functionating and the reflexes apparently normal and only such atrophy as goes with the limited action of the deformed foot, it may be difficult or impossible even to tell which is the primary lesion. We are not always able to obtain a history of earlier paralysis, particularly in the milder cases or in infancy before commencing to walk. I have had several cases in which an early recognized poliomyelitis was the known factor, while in similarly appearing cases no history of a definite attack could be adduced, although it was quite probable that the primary disturbance was the same. Lesions of the nervous system lying both proximal and distal to the portions affected in anterior poliomyelitis may affect similar areas of distribution and initiate the development of cavus. The various forms of neuritis of toxic or other origin may affect the distal elements, and even a primary myositis of the tibialis itself may be responsible for its development.

More obscure are the lesions proximal to the anterior horn cells of the cord lying in any part of the motor route from the cerebral cortex to the termination of the pyramidal tracts. These are usually accompanied by evidences of spasticity, as in the frank cases of Little's disease, yet, just as the mild poliomyelitis may have passed entirely unrecognized, so may a lesion of the upper neurons remain so obscure as never to have suggested its presence. Here a careful study directed to the upper neurons involving both the mental and the motor processes may help to locate the primary seat of trouble.

One of our patients with bilateral cavus and dorsally dislocated toes also had a spina bifida occulta.

The classic symptom-complex of equinus, retracted great toe, and cavus in Friedreich's ataxia is a striking demonstration of this local mechanism. Again, taking the example of the shortened limb with all the muscles physiologically perfect, the constant use of the extended foot develops a compensatory cavus while enabling the toes to reach the ground. High-heeled shoes may thus have a decided influence toward the development of cavus although my experience does not allow me to be positive on this point.

That disturbance of the interossei muscles may lead to the development of cavus was suggested by a recent case in my office of a young woman presenting dorsally retracted toes and complaining of trouble in the anterior region of both feet. The retraction was only slight but the possibility of a later cavus if neglected was mentioned at the time. She was wearing shoes several sizes too short for her. The situation of the interossei, arising from the metatarsals only, prevents their having any direct influence in the form of the arch, but their peculiar function of flexing the first phalanx and extending the last two has a most important influence in maintaining the normal balance between the strong flexors and extensors of the toes. Situated as they are in a part of the foot most commonly abused in the various improper forms of shoes, occasional serious disturbances in their function should not surprise us. Indeed, the wonder is that they do not occur more frequently. With a weakening of these muscles the balance is disturbed and the dorsal extensors gain the advantage. The toes become retracted and the arch increased. Thus the weakness of the smaller muscles destroys the balance and the large muscles produce deformity. A somewhat similar effect on the fingers is well known in paralysis of the ulnar nerve supplying most of the intrinsic muscles of the hand. Local trauma of these muscles may be sufficient to produce these results or their innervation may be disturbed by affections of the nervous structures distributed throughout the lower and upper neurons. There are still cases of cavus in which the origin remains obscure. The mechanism is apparently the same as in those whose origin can be traced, but the etiologic factor eludes detection. These have been considered as due to developmental deficiencies of the nervous system disparaging the normal balance of the muscles and initiating deformities. Other deformities than cavus may thus arise.

Many cases of adolescent cavus appearing in children 10 to 13 or 14 years of age, the so-called true or essential cavus, have been ascribed to this indefinite origin, but it is very probable that the more carefully we search for the many causative factors with which we are already acquainted the fewer will be the number remaining in this obscure class.

### TREATMENT

The treatment naturally resolves itself into that of the general condition and that of the local condition. With most of the cases secondary to previous lesions of the nervous system it is evident that most of the treatment will be of the local condition.

The necessity for proper balancing of the foot is obvious. In the early reducible stage, this is frequently simple, by braces or other means best suited to the individual case or to the practice of the surgeon. In the later, fixed condition, nothing short of very forcible correction will in a measure relieve the deformity. Resection of a wedge from the arch with section of plantar soft parts is often necessary. Various special operations have been devised and used with more or less success in proper cases.

### CONCLUSIONS

Hollow foot, or cavus, is usually accompanied by some malposition of the foot as varus or valgus, equinus or calcaneus. So-called true or essential cavus is rare.

Cavus is practically always of neurogenic origin.

Leaving out of account the paralytic calcaneus and possibly the congenital types, it is safe to assume that a perversion of the normal reciprocal action between the flexors and extensors of the toes can account for most if not all of the remaining types of cavus.

Simple measures commonly suffice to restore the normal balance in the initial stages, while in the fixed deformity severe force, frequently accompanied by resection of bones and section of soft tissues is often necessary to restore in a measure the normal condition of the foot.

## ABSTRACT OF DISCUSSION

Dr. Gilbert L. Bailey, Oak Park, Ill.: This is one of the most common types of deformity with which we have to deal and, while I agree with Dr. Parker about many cases being of nervous origin, my experience has been that the most common type is that with large calluses on the ball of the foot and backward displacement of the toes, for which no central or peripheral nerve origin can be found. More stress should therefore be laid on the disease of the interossei muscles in causing the deformity. This condition is often brought about by the compression of tight shoes or other traumas and it is more analogous to a myostitis than to a neuritis, suggesting Volkmann's paralysis. In many instances a radical bone operation is the only means of curing the condition because treating either the flexor or the extensor tendons seems to afford only temporary relief. When operation is necessary, I have had excellent results with Dr. H. M. Sherman's operation and with Dr. Philip Hoffman's operation for shortening the metatarsal bones.

**DR. JOHN L. PORTER**, Chicago: It is most interesting that many of these cases first develop signs of cavus at about the age of adolescence, and I hope that some day someone will tell us why, if the etiology of the condition is paralytic, it develops at the age of puberty more frequently than at any other time.

I should like to call attention to the operation described and published by Dr. H. M. Sherman several years ago, which, in my hands, has proved efficient; that is, the transplantation of all the extensor tendons from the phalanges into the heads of the metatarsal bones, so that when the lumbricales cease to functionate these act as elevators of the metatarsals. If the after-treatment is prolonged for six months or a year, the action of the dorsal extensors holds up the heads of the metatarsals and makes a satisfactory result.

**DR. EDWIN W. RYERSON**, Chicago: I wish to add a word regarding the usefulness of the operation published by Dr. Sherman. I do not think that he performs his original operation, which has several disadvantages; but it is most useful and, in a late communication from Dr. Forbes, I am told that a slightly different technic was evolved by him and warmly recommended. I have done this operation eighteen or nineteen times, with the best of results. The etiology is, as Dr. Porter says, obscure; but it seems likely that the condition is due, in large measure, to the wearing of improper shoes, which young people, and particularly young women, are forced to wear, because the shoemakers cannot be induced to make proper shoes. The short, narrow portion at the toes predisposes to throwing back the phalanges; and I think that this plays an etiologic rôle in more cases than I formerly believed that it did. I have been unable to find a nerve lesion in many of the cases, and it is hard to theorize as to why the interossei should be paralyzed with no paralysis anywhere else. I think that the condition is one of static rather than paralytic deformity in many cases.

**DR. NEWTON M. SHAFFER**, New York: The point raised by Dr. Porter about the cases occurring at the period of adolescence recalls what I have thought for many years; and that is the peculiar fact that this condition of the feet and lateral curvature both develop at about the same age. My study of these cases has been, I think, wrong; and I believe that you will find in almost every case some disturbance of the tendo Achillis. With the calcaneus variety of the deformity, the heel is thrown forward; in others, the tendo Achillis is shortened. In a certain class, we have hollow foot; and in other cases, we have flatfoot. It all depends on the tonicity of the plantar tissues. In the nervous variety, these tissues are resistant, and in other cases the nutrition is low and the foot gives way and flatfoot follows. In all cases, I think, the tendo Achillis is involved. It is short in many cases; and that led me to describe a condition, some years ago, called non-deforming clubfoot. The tendo Achillis plays an important part in all these conditions.

**DR. JOHN RIDLON**, Chicago: I am sorry to see that Dr. Parker's efforts and this discussion have not led to any more intelligent knowledge of the situation than we have had heretofore. Apparently it is impossible to get the idea of what a real hollow foot is into the heads of most men. Dr. Shaffer's non-deforming clubfoot, which I have known of for thirty-five years, has absolutely no relation to the condition that Dr. Parker has tried to write about. To be sure, pes cavus usually begins to develop at about the age of adolescence; to be sure, lateral curvature of the spine is usually recognized at about that time, but it has been developing for a long time. But one cannot conceive of any real relation between the two.

The shoes of women are frequently ridiculous and quite unlike the feet of any normal person; but the fact that they wear high heels has never, so far as I know, been a causative factor in pes cavus—I have never seen a pes cavus in a woman wearing high-heeled shoes. I prescribe more high heels than low heels for the women that come to me complaining of their feet. As a matter of fact, pes cavus rarely ever occurs in women. It practically always occurs in males—in adolescent boys. Dr. Porter will remember, I think, that he and I felt surprised at finding in a patient of his from Iowa the first case of pes cavus in a woman that he and I had ever seen. The view that there is a relation between the condition and high-heeled shoes, or pointed-toed shoes, is certainly a mistaken one. We do get, in the women who wear such shoes, feet with the toes bent backward, and also other deformities of the feet; but that condition is not under discussion, any more than Dr. Shaffer's non-deforming clubfoot is.

**DR. CHARLES A. PARKER**, Chicago: I knew that some interested member would be much disappointed in the results of my paper. It was founded, however, on my experience. I had seen cases of cavus of different origins, and, as I came to study out the problem, one of the first things that came to me was the mechanism of cavus. I looked over case records and found that I had never seen a case of cavus of the type of adolescence. That is why I did not write on it. I have seen these patients when they were old, but never happened to follow them through the adolescent period. I, therefore, dropped out that part of the subject from the paper, and included only the types of the condition that I could study out for myself, although I had read the papers of Dr. Shaffer and others.

The point that I believe will stand is that the essential factor in the mechanism, without going further, which I hope sometime to do, is the disturbance of the balance between the flexors and extensors of the toes, arising either in the muscle, the nerve, the spinal cord or the brain.

# FIELDS FOR RESEARCH IN ORAL SURGERY *

VIRGIL LOEB, A.B., D.D.S., M.D.
ST. LOUIS

To discuss the various possible avenues of research in that branch of medicine known as stomatology would require a paper the reading of which would far exceed the time allotted to me. I have, therefore, selected a single division of this branch, and shall confine myself entirely to the discussion of some of the fields for research which are still not definitely worked out in oral surgery. To facilitate this discussion, the investigative fields are divided into five classes: embryologic, anatomic, bacteriologic, physiologic and chemical. Moreover, I shall not attempt to enumerate or to discuss all of the problems in each class, but shall mention only a few of the more important ones.

The embryologic problems for study comprehend the following: cleft-palate, harelip, fistula of the lip, fissure of the tongue, fissure of the cheek, facial asymmetry and congenital teeth, of which cleft-palate and harelip, alone or combined, are the most frequent. A great deal of work has already been done on the etiology of the latter deformities; cleft-palate has even been produced experimentally in animals.

Many theories have been advanced as to the cause. That family prevalence as an important factor was long ago established by cases reported by Mercer Adam,[1] notably of a woman whose five children all had harelip, and by Merkel[2] in his reference to Anna's observation of a man who had by his first wife eleven children, nine of whom were born dead, and two alive, with harelip and by his second wife four children, two of whom had the same deformity, and one cleft-palate. Direct heredity is noted in the case of R. G. H. Butcher[3] in which both mother and child had double complicated harelip with entire absence of the palate. Many more cases of heredity have been noted in more recent times.

---

* Chairman's address before the Section on Stomatology of the American Medical Association at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

P. Albrecht[4] pointed out the fact that the commonest position for cleft of the alveolar arch, accompanying harelip, corresponds to the interincisor suture, running through the premaxilla and separating the central from the lateral incisor teeth. Formerly it was the belief that the fissure in the bone corresponded to the suture between the premaxilla and the superior maxilla and that therefore the incisor teeth (after eruption had taken place) lay internal to it. Ballantyne thinks that too much significance is given to the morphology of the incisor teeth in arguments for and against Albrecht's views. He[5] says,

> After all, it is not to my mind an unthinkable theory that the cause, which arrests the development of the face and makes permanent what ought to be a transitory arrangement of parts, may also act on the dental germs in the jaw and lead one germ to atrophy and another to increase in size and perhaps divide in two. The facts of embryology must first be thoroughly investigated (teratological developments being utilized as hints to direct research), and then the general principles of teratogenesis must be applied to the scrutiny of the results: if this be done, I feel sure that the actual mode of production of harelip and all other malformations will be made plain. Of course this does not mean that the cause which leads to the arrested developments will be discovered, although we may be in an infinitely better position to make surmises regarding its nature; we shall then, I expect, find we are dealing with the germinal factor.

Continued work along this line with similar investigation concerning the other anomalies of development should yield results of great value.

Anatomically, a number of interesting fields present themselves for investigation. Certain surface areas are yet to be determined. It would be of service, for instance, to know the surface area of the hard and soft palates and of the tongue. Last year I presented a paper[6] before this Section, and I had hoped to present at this meeting a paper on the superficial area of the palate; but as my data are not sufficiently complete, I am compelled to postpone it.

The papillae of the tongue offer interesting problems for investigation. The studies of the arrangement of these papillae, especially the vallate, by Giacomini, Stahr, Hopf and Edzard, and Kunitomo[7] seem to show that fairly well-defined types exist in the white and colored races. This deserves further study.

Another anatomic problem concerns the exact location of the pharyngeal end of Rathke's pouch. That this is worthy of investigation has been shown by Frazer.[8]

Much might be gained by a comparative study of the musculature of the lips and tongue in the various races and the physiologic significance in pronunciation, while the distribution of the lymph-vessels in the walls of the mouth and in the tongue and soft palate is worthy of renewed study.

The bacteriology of the oral cavity has been pretty definitely worked out by Miller,[9] who described more than forty germs which he had isolated. He admitted that there were still others to be studied.

Such problems as the ages (of persons) at which the different micro-organisms appear, the relative virulence at different ages, the influence of the accumulation of deposits around the roots of the teeth on the production of these germs, and vice versa, are all of importance. Specific germs which cause caries and certain cases of the so-called pyorrhea alveolaris are yet to be determined.

Recently a great deal of attention has been drawn to the relation which the absorption of toxins from different forms of alveolar abscess bears to arthritic disturbances and other toxic manifestations in various organs of the body. Concentrated investigation along this line should yield results which will prove of great value in the diagnosis and treatment of many obscure and even remote conditions.

The saliva presents a number of important physiologic problems for investigative work.

Goodman[10] asserts that the sputum of tuberculous patients contains albumin. Normally the saliva and sputum do not contain this substance. The assertion made by Goodman which has been denied by other workers will bear further investigation in order to determine the significance of albumin in pulmonary tuberculosis.

Neubauer and Fischer[11] and Sanford and Rosenbloom[12] all assert that in carcinoma of the stomach there is an enzyme present which splits up glycyltryptophan. Warfield[13] and others assert that there is in the normal saliva the same enzyme which does the same thing. This is of such vast importance to the clinician that further work should be done to substantiate or to disqualify Warfield's statement.

Quite a little work has been done on the sulphocyanid which is found in the saliva. This substance is found in excess in smokers and it is a question as to whether or not it is due to some metabolic process.[14]

Fricker's[15] work opens up a new problem: Is the saliva a stimulant to the gastric juice? If so, is it due to carbon dioxid as he suggests or to the presence of a hormone? The view that the latter theory may be true fits in well with the work of Bayliss and Starling, that many of the body functions are due to the influence of the so-called hormones.

Another field for investigation concerns the formation of tartar. Is the ordinary explanation correct? Are the calcium salts, held in solution, precipitated by the action of the carbon dioxid in the saliva, or is tartar due to some other chemical action, or perhaps to bacterial action?

Of course this problem should perhaps come under the chemical or bacteriologic subdivision which I have made for the classification of research work, but it also concerns the physiology of the saliva.

So much significance is given to the urine and feces, does it not seem plausible that the time will come when the saliva, too, will undergo a routine examination as do these two excretions?

Fields for research in the oral cavity, of a purely chemical nature, are perhaps less numerous than those of the other divisions. Mention has already been made of formation of tartar. Under this head would also come a study of the combinations which are formed by the action of the different tooth-powders and pastes and mouth-washes which are used so generally by the public. The chemical combinations resulting from such mixtures may play a part in the production of certain oral lesions, particularly those of a purely dental nature.

The etiology, diagnostic relations and treatment of several diseases of the oral cavity are still uncertain, and for this reason offer a promising field for research. Among the more important ones the following are worthy of study: trifacial neuralgia, stomatitis aphthosa, leukoplakia, ankylosis (certain types), pyorrhea alveolaris or interstitial gingivitis, chronic enlargement of the salivary glands, particularly the parotid, scurvy, noma and malposed teeth.

I have brought this subject to your attention for the purpose of urging on you the great necessity for encouraging work along the investigative side of oral surgery. Until those who are devoting themselves to this subject impress on their students and associates the full value of research in this connection, we are bound to become routinists and no progress can be made.

537 North Grand Avenue.

## ABSTRACT OF DISCUSSION

Dr. F. B. Moorehead, Chicago: One thing ought to be said about research, and that is that it cannot be bought; neither can original investigators be bought. The original worker, like the poet, is born, not made. A peculiar fitness for that kind of work must be inherent in the individual. When a man has been in practice for a few years and has become fixed in his habits, he is not likely to change. Our only hope lies in the undergraduate student, who is still in the *formative* period. I believe that the hope of the future is in selecting students who have the scholarship, the vision, the inclination and the natural ability to do original work, and in starting them out before they become established in the routine of dental practice. We must also remember that the medical profession is taking as much interest in the oral cavity in its relation to the composite organism as is the dental profession, perhaps more in some instances. The dental profession should take the initiative in this work. We should point out the relation of the oral cavity to systemic disease. We ought to do as much for the oral cavity as the eye specialist has done for his work and as the ear, nose and throat specialist has done for his work. We have not done it, and the fact of the matter is that at present we are being driven into the corner by the medical man, and, like a stag at bay, we are now fighting absolutely in defense of our position.

The medical college of to-day is paying more attention to the oral cavity than it has ever done before, and more work is being done by the undergraduate medical student in this line than ever before, and that is significant. May it not be true that if we do not do our work, the medical men will take it on themselves to develop the diseases of the oral cavity as a special field of practice?

Dr. Truman W. Brophy, Chicago: When in the history of our country it became necessary to create currency for the use of the people, greenbacks were issued in enormous quantities. The currency was increased to a degree that brought the value of a dollar down to about forty cents in the estimation of the world. When the time came for returning to specie payment, the president of the United States decreed that the only way to resume specie payments was to *resume*, the advice of many statesmen to the contrary notwithstanding; so the nation resumed specie payments. So, when it comes to the question of scientific development, the only way to acquire information along scientific lines is to acquire it, and the way to acquire it is to have men do that work who are well prepared and placed in the proper environment to do it. As Dr. Moorehead said, a busy practitioner cannot devote much time to laboratory work. As a rule, he has neither the time nor disposition to do it. Men must make that work a business. I shall expect in the next decade to see such institutions as the Forsythe Laboratory established in Boston with a liberal endowment, and the Thomas W. Evans Institute, which also has a liberal endowment, gather together men prepared to engage in scientific work. Unfortunately, in our own country few men have taken up the study of that branch of pathology particularly associated with the mouth.

Dr. T. L. Gilmer, Chicago: The paper is timely. It would be impossible for us to discuss some of the things presented because there has not been sufficient development to arrive at definite conclusions.

Dr. Moorehead spoke wisely when he said that research work cannot be bought. When we look back over the history of medicine and that branch which we represent and consider the men who have made the great discoveries, we see that they have not been hired men. To do original research work, a man must be especially fitted for it, by temperament and by nature. He must have a zeal for his work that is overpowering; then he succeeds. Such men are not made; they are born.

I am doubtful as to the utilization of students for this work, since it seems impracticable to expect good research work of men who have had no practical experience. Indeed, one should have had much practical experience, otherwise he will not know the full value of that for which he looks. If young men in their college work exhibit inclination for research work they should be stimulated and encouraged in that direction.

There is one class of men specializing in dentistry at present to whom I think this paper should appeal. I refer to those who call themselves "pyorrhea specialists." I have no patience with any man calling himself a specialist who is not doing good research work in his special field. Are all pyorrhea specialists as a class well informed in histology, pathology and bacteriology of the special tissue they operate on? If they are not, they are not worthy of the name of specialists.

Dr. William C. Fisher, New York: Speaking of buying research work, the First District Dental Society of New York has secured the services of the most eminent physiologic chemist in the East, and he has for two years been working on the saliva. He has given us few facts in that time, and the reason is that he is not a stomatologist or a dentist. He is a chemist.

The dean of one of the largest dental departments of a university in the East told me over a year ago that for the past seven years he has gone to every class and watched it carefully in order to find a man of whom he can make a research worker, but he has not found him.

Dr. G. V. I. Brown, Milwaukee, Wis.: As suggested by Dr. Brophy, there are now a number of propositions leading toward the establishment of laboratories in which work of this kind can be done. They must have an endowment which will permit them to pay persons to carry on this work. As has been said, a man who is busy making a living cannot devote himself to research work, and a man's education to fit him for this work should begin early; but the trouble is that the men who have the education and who have the time are often men who have not had the foundation of a practical experience which teaches them to know the direction in which their researches can be carried on to best advantage. Those who have felt the need of this kind of work should give it definite, concerted and systematic thought, so that these various projects may be launched successfully and in a direction which will yield the greatest good in the shortest possible time.

Dr. Nelson T. Shields, New York: In research work, and especially in research work with regard to the oral cavity, which lies so near the central nervous system, if we would bend our efforts in the direction of the neuropathologist we should find that the origin of pyorrhea, etc., results directly from the degeneration of the entire system, caused by the fact that the night's rest is not sufficient to restore the loss of tissue which takes place during the day.

Dr. William H. DeFord, Des Moines, Iowa: I have been doing research work for a number of years and consequently am much interested in this matter.

Dr. Loeb's warning is timely. We should take greater interest in these matters pertaining to our everyday work, because, if we do not, the medical men will do it first, for they are fast entering this field of investigation which rightly belongs to the stomatologist and dental surgeon. Recently, Dr. Charles H. Mayo emphasized the danger of local infections resulting in constitutional disturbances, and he warned the dental profession that unless they were active in working out the etiology of pathologic conditions found in the buccal cavity the medical profession would certainly do it for us, and the credit would be theirs. I am heartily in accord with the work being done by the research committee of the National Dental Association. If the right men can be induced to devote their lives to working out these problems for us, giving us the results of their labors, it will meet with hearty approval, but I hope that this will not interfere with individual research work. We should not rely entirely on the work of professional research investigators. The outline furnished by Dr. Loeb is a most excellent one, and no doubt it will stimulate men to go into these matters more thoroughly than they have done in the past.

Dr. Virgil Loeb, St. Louis: When I chose this subject, I felt that the question of research work was so important that it could not be brought before the profession too often. When I started to write the paper, however, I found that it was indeed quite an undertaking to outline the various branches of work which are open for investigation. The discussion has brought out a number of points which I could not incorporate in the paper. One is the question of who should do this work; another is the question of how it should be done.

It has been said once or twice in the discussion that the busy men cannot do research work. I think that it is he alone who should do it. It is the man who is in contact with definite problems daily who can determine the principles which must be worked out.

# THE ETIOLOGY OF TRIFACIAL NEURALGIA OR TIC DOULOUREUX AND CLINICAL TREATMENT *

NELSON T. SHIELDS, D.D.S.
NEW YORK

The fundamental cause of trifacial neuralgia lies in some structural change. The really painful tic usually occurs about the period of middle life or later and is generally caused by a lesion or lesions within the teeth. All strain, whether mental or physical (and this comprises that common to all diseases and conditions), which a normal amount of sleep cannot relieve or during which the tissue consumed cannot be restored, these abnormal conditions are the foundations for an earlier degeneration of the nerve structure. No injury to the teeth from external causes, and no injury to the dental pulp from constitutional causes ever repairs itself. That is, should a tooth be broken or decayed it can never be restored by natural means, or should a pulp nodule or dentinal tumor form within the pulp from constitutional causes it will never be absorbed. A normal life should be led more on account of the teeth than any other organs of our bodies, because within the teeth branches from the maxillary nerve and from the mandibular nerve terminate within an organ, the function of which is to make tooth structure from without inward, after the manner in which teeth are formed.

The odontoblasts within the dental pulp (the pulp being the remainder of the formative organ which made the tooth) receive the irritation from any local injury and cause tooth structure to form within the pulp at the base of the fibrillae conducting the irritation. This is most dangerous at the cervix where the blood has to circulate around the secondary dentine to the pulp chamber beyond. The odontoblasts likewise cause calcifications to form within the pulp from any constitutional cause which affects the vasoconstrictor nerves, a consequent increased flow of blood through the arteries results, followed by their dilatation and the immigration of the leukocytes. Thus the arteries occupy more than their normal space in the canal, while the leukocytes fill the meshes of the connective tissue and produce compression on the vessels of exit. This irritation or hyperemia will cause pulp nodules or tumors to form throughout the entire pulp causing lesions and violent tic douloureux before strangulation occurs.

Frequently, in severe cases, the teeth, the alveolar process and gums are in perfect condition save the abrasion on the articulating surfaces which is normal after the period of middle life. We must, therefore, in these cases, look for internal causes for irritation which are to be found in the presence of dentinal tumors or pulp nodules. These patients are about 60 years old and have a poor circulation. The family physician having exhausted all means of relief, the patient is about to be operated on either by having alcohol injected or by avulsion of the sensory root. General nervous irritability or neurasthenia is a term which has come into general use to indicate certain states of the nervous system which are characterized on the one hand by a series of negative symptoms manifested by lack of vigor, efficiency, and endurance, affecting usually a large number of nerve functions, and on the other hand, by signs of active derangement, which in part seem to occur as positive symptoms and in part are due to a failure of the mutual support and control which the different parts of our nervous system afford each other in health. The tension of the blood-vessels and their degree of contractivity are phenomena which are controlled by the vasomotor system.

We can generally find lesions within the pulps of teeth, where impacted teeth become infected, diseases of the teeth, alveolar process and gums, and maxillary and frontal sinus complications which are generally caused from the affected teeth.

The knowledge is valuable that any constitutional condition affecting the vasomotor system will cause irreparable injury within the dental pulp, and that the formation of tumors or calcifications in the structural change, or lesions which will result in trifacial neuralgia or tic douloureux.

### TREATMENT

In simple cases a careful study will clearly indicate the teeth or tooth, which is the cause of the neuralgia. The pulps of the teeth involved should be extirpated by pressure using cocain anesthesia. After thorough extirpation by mechanical means, using suitable broaches, asepsis being maintained throughout, the apical portion of the root-canal should be filled with gold and the remaining portion should be filled with zinc oxychlorid. The zinc oxychlorid not only fills the remaining portion of the root-canal, but from its affinity for moisture, practically fills the dentinal tubules. This constitutes in my estimation a perfect root filling.

* Read in the Section on Stomatology of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

* This is an abstract of the original paper presented before the Section on Stomatology, which was an exhaustive one and too long for the columns of The Journal.

This case will remain free from neuralgia until a lesion is formed within another tooth, when the same method of procedure should be employed. In severe cases of tic douloureux radical measures should be employed, and every pulp should be extirpated, the teeth filled as described and the mouth should be restored to normal health and usefulness. This will permanently cure.

Children suffering from the migraine type as described by Dana will generally be found to possess impacted teeth which should either be regulated to their normal positions or extracted.

By means of roentgenography infected impacted teeth can be revealed and then extracted. In most cases tic douloureux occurs after the patient has reached the age of 45, and has a poor circulation. I strongly urge the use of agents to induce a normal secretion of bile, which will favor restoration to health.

Maxillary sinus complications are generally caused from the teeth. Occasionally the frontal sinus is connected with the maxillary sinus, as has been demonstrated by Dr. Cryer in a number of human skulls. The tooth or teeth causing the sinus involvement should be extracted and the sinus treated and cured through the tooth socket. Both sinus involvements on the same side can be cured from the socket of the tooth extracted. A sinus involvement should always be cured through a tooth socket.

This treatment in my hands has been a permanent cure for trifacial neuralgia or tic douloureux.

# TYPHOID FEVER IN THE CANAL ZONE

## A STUDY OF ONE HUNDRED AND NINETY-FIVE CASES FROM THE CLINICAL AND BACTERIOLOGIC POINTS OF VIEW *

WALTER G. BAETZ, M.D.
AND
LEWIS B. BATES, M.D.
Physician and Bacteriologist, respectively, Ancon Hospital
ANCON, C. Z.

Climate, locality and race are known to affect various diseases to an extent that at times confuses the diagnostician who holds to the classical description of the disease in question. A study of 195 cases of typhoid fever occurring in this hospital from July, 1909, to July, 1913, was therefore thought to be of interest to the profession. Permission to write this joint paper was kindly granted by Dr. W. E. Deeks, chief of the medical clinic, and Dr. S. T. Darling, chief of the board of health laboratories.

Three papers[1] have previously been devoted to typhoid as found on the Isthmus of Panama during American occupation. These papers were presented prior to 1909, so that the following series represents another four-year period of American régime.

The cases under consideration in this paper have been collected from a section of Ancon Hospital in which the majority of the typhoid fever patients of the Canal Zone have been treated.

As to race the total series comprises 174 West Indian negroes, 9 Colombians, 6 white Americans, 3 Spaniards, and 1 Ecuadorian, 1 German and 1 Italian.

Practically all of the patients cited were young male adults employed as laborers in the canal construction. This is not due to case selection, but is the result of importation of young adults only. None of these laborers have ever had antityphoid vaccination.

During the four years covered by this paper there has been no epidemic of typhoid fever in the Canal Zone nor in the cities of Colon and Panama. A few of the cases included are the remainder of a small epidemic occurring in the early part of 1909. In this epidemic about 50 per cent. of the cases were found to be paratyphoid infections. These will be referred to later.

The fact that the great majority of our patients are tropical negroes gives us the advantage of observing the disease as it runs its course in natives of the tropics. On the other hand, we are at a disadvantage in obtaining accurate data from these patients concerning their illness prior to admission to the hospital. Our negro's idea of time and illness is very vague indeed. The onset of an insidious disease like typhoid fever is frequently difficult to obtain approximately correctly from an intelligent Caucasian. In the negro this amounts almost to an impossibility, as he habitually underestimates the time he has been ill. In the charts and tables shown the division of the disease into the customary periods of four weeks is based entirely on the negro's faulty history. We were forced to accept this method after having found all other schemes impractical.

### DIAGNOSIS

The history as given by the negro patient is generally of no practical value and must be disregarded in most instances. As previously stated, a patient admitted at the end of the first week rarely claims more than three or four days' illness. Fever, headache and loss of appetite are usual complaints, but no more so than in malaria and many other minor affections. Vomiting is an infrequent complaint, especially when compared with malarial infection.

Physically we may find a patient who *does not* seem ill and who protests against having been ordered to the hospital for a slight rise in temperature, or, on the other hand, he may have been sent to the hospital in a deep coma. Either case may be in the first or last week of the disease. As a rule the thermometer shows only slight fever in the ambulatory type, but usually high fever or hyperpyrexia in the semicomatose and comatose types. The tongue is frequently heavily coated and often distinctly tremulous. The spleen was found to be enlarged, either by palpation or percussion, in 75 per cent. of our cases. The value of splenic enlargement in a tropical community is practically nil in its diagnostic significance, unless previous and present malarial infection can be definitely excluded. With rare exceptions, rose spots are imperceptible in the negro. Profuse sweating was not uncommon in our typhoid fever cases, but differed in no way from infections like malaria and tuberculosis. Diarrhea and tympanites, with the usually associated iliac gurgling, were the *exception* and *not* the rule in our cases. Epistaxis was a very rare symptom. Early in the disease a slow pulse as compared with the height of the fever was strikingly common, and quite distinctive from severe malarial and tuberculous infections. Later in a severe infection, rapid pulse and dicrotism of course supervened. Neurologic findings, that is, stupor, delirium, meningism or coma, vary greatly. They may be entirely wanting or they may form the most conspicuous feature of the disease. Albumin and casts were found on analyzing the urine, as in most other acute infections. We have kept no records of the diazo reaction.

---

* Read at the monthly session of the Medical Association of the Isthmian Canal Zone, July 19, 1913, and published with the permission of Col. W. C. Gorgas, U. S. A., Chief Sanitary Officer, and Lieut.-Col. Chas. F. Mason, U. S. A., Superintendent of Ancon Hospital.

[1] Bates, J. P.: Atypical Typhoid Fever, The Journal A. M. A., Feb. 22, 1908, p. 585. Deeks, W. E.: Typhoid and Allied Fevers in Panama, Proc. Canal Zone Med. Assn., 1909. Brown, T. R.: A Brief Review of Some of the Work in Ancon Hospital on Typhoid and Allied Fevers, ibid., 1909.

The temperature course of our typhoid fever cases was as variable as the disease itself. The classical four-weeks fever curve was the usual type. Of the remainder, the majority ran a lower and more abbreviated curve. The protracted cases have usually been severe infections and have continued as long as seven weeks. Relapses have occurred both during the attack and after. Twenty-four, or about 12 per cent., of our cases relapsed. There was only one fatality in this number. All relapses were shorter than the primary infection. Recrudescences were few and of no importance. Typhoid fever usually confers lasting immunity against subsequent attacks, but this is not invariably the rule. A very interesting illustration of this fact occurred in our series (Charts 1 and 2).

A young Ecuadorian half-breed, S. R., was admitted Feb. 13, 1911, suffering with a typical case of typhoid fever. The Widal reaction was negative on the second day after admission. A blood-culture taken on the fifth day was sterile. The Widal was repeated on the thirteenth day after admission, when it was positive. The temperature returned to normal in the fourth week of the disease and convalescence was uneventful. The patient resumed his work, but again became ill and returned to the hospital April 1, 1911. He was seriously ill and typhoid fever was again suspected clinically. A blood culture taken on the third day was positive for *Bacillus typhosus*. The Widal was also positive on the fifth day. A severe typhoid fever course followed with alarming hemorrhage. During the third week an intercurrent relapse took place and the prognosis became grave. On the twenty-seventh day in the hospital the blood-culture was found to be positive for *B. typhosus* as before, while the formerly positive Widal reaction had become negative, suggesting a reinfection due to a repeated loss of antibody. Death occurred with hyperpyrexia on the thirty-fifth day. A necropsy performed by Dr. Herbert C. Clark, pathologist of the board of health laboratories, showed the following: Acute and chronic ulcerative enteritis of the ileum; acute ulcerative colitis of the cecum and ascending colon; multiple congested and edematous, coin-shaped cicatrices of the ileum and jejunum and the other usual findings of typhoid fever. Post-mortem cultures from the spleen were positive for *B. typhosus*.

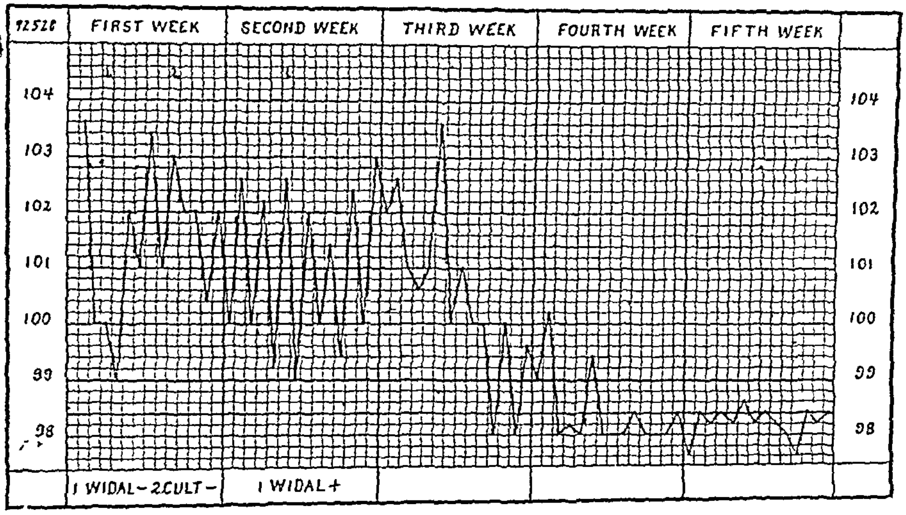

Chart 1.—Primary attack of typhoid fever resulting in recovery

The leukocyte count was performed 198 times in uncomplicated cases, giving an average of 6,750. In no uncomplicated case was there a count of over 11,000, but absence of leukocytosis did not exclude complications. This forcibly demonstrates the value of the leukocyte count in detecting the complications in the course of typhoid infection. Differential white blood-counts were not undertaken.

The exact value of the Widal test in the diagnosis of typhoid fever seems difficult to estimate. A positive reaction preceded by a negative one during the course of a fever suspiciously like typhoid is of undoubted value. To illustrate this point, the last case of our series may be cited:

The patient was admitted in what later proved to be the terminal part of the disease. His infection had evidently been a rudimentary one. Slight fever, a coated tongue and a low leukocyte count were the only physical findings. Typhoid fever in the decline was suspected and a Widal test made. The result was negative. A repeated test was also negative several days later. The fever, ending by lysis, seemed to confirm the clinical diagnosis and a third Widal was made during convalescence. This time the result was positive. A proof of the correctness of the Widal in this case was obtained four days later when a relapse occurred during which the blood-culture was positive for *B. typhosus*.

On the other hand, it is a well-known fact that the Widal test in even a single case may vary from day to day, being positive one day and negative the next. It is therefore not surprising to us that 103 tests on ninety-eight cases in the second and third week, though positive in 89 per cent. of the total cases, are difficult to analyze.

The absence of history of previous infections and the constantly increasing number of antityphoid vaccinations invalidate this test in another group of cases. Another source of error is the unfortunate fact that in unselected cases not suffering with either typhoid fever or tuberculosis, over 15 per cent. gave a positive test. Whether or not this percentage of our negroes have had typhoid fever in their native islands we have no means of ascertaining. Finally, the Widal test may be positive in tuberculous patients, for it is a fact that not a small percentage of our disseminating and miliary tuberculosis patients give a positive test. To confirm this clinical experience, the Widal test was performed on thirty-two patients with positive tuberculosis in the advanced stage. Of these thirty-two tests, seven were positive, four gave partial agglutination, and twenty-one gave negative results.

The following technic was employed in all tests: One drop of the patient's serum was diluted twenty-five times with normal saline solution. One loopful of this diluted serum was thoroughly mixed with one loopful of a saline emulsion of a twenty-four-hour agar slant growth of *B. typhosus*, this giving a 1:50 dilution of the serum. This mixture was prepared in the form of hanging drop and observed at half-hour intervals, two hours being the maximum period allowed for agglutination to occur.

The blood-culture is the only absolutely positive diagnosis of the disease. It was found to be positive in 80 per cent. of our cases cultured during the first week, 53 per cent. in the second week, and 34 per cent. in the third week; too few were cultured in the fourth week to warrant conclusions. Out of a total of 126 positive cases, *B. typhosus* was recovered 106 times; *B. paratyphosus* A 10 times; and *B. paratyphosus* B 10 times. Seven each of the two latter were recovered in 1909, a year which showed 50 per cent. paratyphoid infection during a small epidemic. Generally speaking, the earlier the culture is taken the higher the percentage of positive results. (Table 1 and Chart 3).

TABLE 1.—BLOOD-CULTURES

| Day of Disease | Number Cultured | Positive | Negative |
|---|---|---|---|
| 1 | 0 | 0 | 0 |
| 2 | 0 | 0 | 0 |
| 3 | 2 | 2 | 0 |
| 4 | 4 | 3 | 1 |
| 5 | 5 | 3 | 2 |
| 6 | 12 | 10 | 2 |
| 7 | 21 | 17 | 4 |
| 8 | 16 | 12 | 4 |
| 9 | 30 | 17 | 13 |
| 10 | 18 | 9 | 9 |
| 11 | 22 | 9 | 13 |
| 12 | 19 | 11 | 8 |
| 13 | 12 | 7 | 5 |
| 14 | 9 | 2 | 7 |
| 15 | 4 | 2 | 2 |
| 16 | 9 | 3 | 6 |
| 17 | 3 | 1 | 2 |
| 18 | 5 | 1 | 4 |
| 19 | 4 | 2 | 2 |
| 20 | 2 | 1 | 1 |
| 21 | 2 | 0 | 2 |

The blood-culture has been positive in all our fatal cases with one exception. In this case *B. paratyphosus* A, and not *B. typhosus,* was recovered from the spleen at necropsy, though the ante-mortem culture remained sterile. It occasionally happens that the first blood-culture remains sterile, while a subsequent one proves positive when culturing the usual amount of from 5 to 10 c.c. of venous blood. The culture was positive in twelve out of thirteen cases examined during relapse. Three of these positive results were *paratyphosus* B, and two *paratyphosus* A, the remainder being *B. typhosus.*

The technic employed in recovering and identifying *B. typhosus* from the blood-stream was as follows: About 12 c.c. of blood were taken under aseptic precautions from a vein at the bend of the elbow, 5 c.c. being placed immediately in 50 c.c. of bile glycerin peptone medium, 5 c.c. in broth containing 0.6 per cent. ammonium oxalate to prevent clotting, 2 c.c. in 50 c.c. of litmus milk and several drops on agar slants. The latter two mediums were not used for recovering the typhoid bacillus, but for those organisms which will not grow in the bile or beef medium. Bile is undoubtedly the best medium for the recovery of the typhoid bacillus. These mediums were incubated at 37 C. from eighteen to twenty-four hours, at which time six agar plates were poured, three of the plates being inoculated with various dilutions from the bile medium and three from the broth. If at the end of twenty-four hours' incubation typical dew-like colonies were present on these plates, the organism was considered to be *B. typhosus,* but the work of identification was continued. (Colonies direct from the plates were occasionally tested with immune serum.) Several tubes of broth were inoculated each from a different colony and these incubated over night to obtain an abundant growth of the organisms. Each tube was then used to inoculate an agar slant, litmus milk, broth, potato, Dunham's mediums and the following semisolid mediums: dextrose, lactose, dulcite, saccharose, galactose, mannite and dextrin. A gelatin stab was also inoculated if the organism was not typical in every respect. A reading of these mediums was made every day for ten days, at which time the peptone mediums were tested for indol, agglutination tests were performed with immune rabbit serum and the agar slant sealed and filed away for further reference if necessary.

The typhoid organisms recovered from the cases cited in this paper have shown identical cultural characteristics in all but a few instances, namely: No gas formation in any mediums, acid formation in glucose, galactose and mannite semisolid, also in maltose when used; all this taking place in from twenty-four to forty-eight hours. There was turbidity and sediment in beef tea, a slight lilac tinge to the litmus milk, no indol in the peptone medium, an invisible growth or faint white streak on potato and the usual growth on agar slant. The bacillus has been easily agglutinated by immune rabbit serum and in dilution of 1:200.

The paratyphoid bacilli, as a rule, have fermented glucose, dulcite, galactose, mannite and dextrin with the formation of both acid and gas. The formation of gas in the galactose and mannite semisolid mediums has not been constant; it sometimes occurring in one, sometimes in the other, sometimes in both and sometimes in neither. Also, fermentation with a slight production of gas, a bubble or two, has been observed in lactose semisolid. Very rarely has this occurred in saccharose medium. Several colonies from the same plate may show all these differences. Cultures showing these variations were also taken and identified during the epidemic in the spring of 1909 by Dr. S. T. Darling.

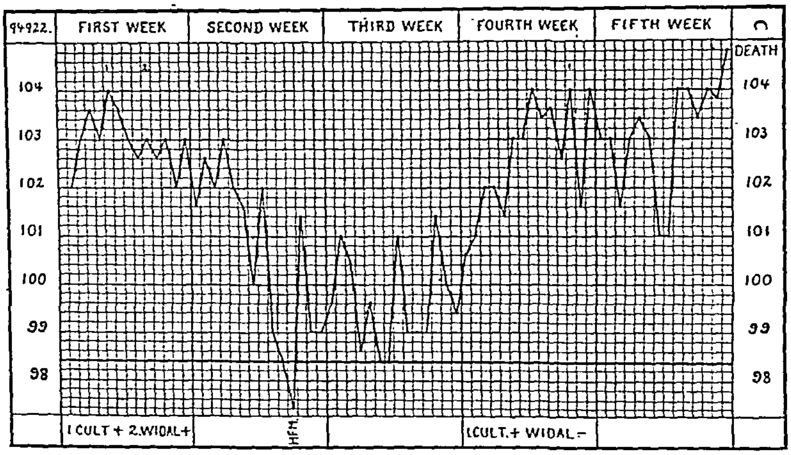

Chart 2.—Second attack of typhoid fever in same patient, several weeks later, followed by relapse and death.

In the A type the milk remained slightly acid, while in the B type it became strongly alkaline in most instances about the fifth or sixth day. The identification of each organism was completed by testing it with the respective immune serums in high dilution.

In all probability in none of the straight typhoid cases has there been a simultaneous infection with paratyphoid organisms, as glucose semisolid medium has been inoculated directly from the bile medium in a large number of cases, and in none has gas production been observed.

Early in 1909 Lieut.-Col. Charles F. Mason, superintendent of the hospital, issued orders to have stool and urine specimens cultured for *B. typhosus* during convalescence. In the submitted series 399 stools and 401 urine specimens were cultured. Tables 2 and 3 show the results obtained.

TABLE 2.—TOTAL OF THREE HUNDRED AND NINETY-NINE STOOL CULTURES

| | |
|---|---|
| *B. typhosus* present in | 16 |
| *B. paratyphosus* A present in | 1 |
| *B. paratyphosus* B present in | 0 |

TABLE 3.—TOTAL OF FOUR HUNDRED AND ONE URINE CULTURES

| | |
|---|---|
| *B. typhosus* present in | 13 |
| *B. paratyphosus* A present in | 3 |
| *B. paratyphosus* B present in | 0 |

In twenty-eight cases, or 14 per cent., *B. typhosus* or *paratyphosus* were recovered from the stool or urine or both. In these twenty-eight it occurred but once in twenty-five cases, twice in two and repeatedly in one.

### DIFFERENTIAL DIAGNOSIS

There are several infections which in many ways so closely simulate typhoid fever that a differential diagnosis is at times difficult. Of these, three deserve special attention, namely, malaria, disseminated or miliary tuberculosis and a class of cases which we have always been forced to designate "acute infections of undetermined origin."

Malaria, severe enough to be mistaken for the average typhoid fever in the fastigium, can almost invariably be diagnosed by the examination of a Romanowsky stained blood-film (Hasting's stain has been the stain of election in the Canal Zone), provided that quinin has not been previously administered. Even in cases in which the urgency of symptoms seem to indicate immediate quinin administration, there is no excuse for neglecting to make a blood-film first, for future examination. Should this simple precaution not have been observed, it may become necessary to apply the therapeutic test of from four to six days' heavy quinin administration in the face of negative blood examinations. The dosage of quinin necessary to combat a pernicious malarial infection cannot but be detrimental to a patient who is actually suffering with typhoid fever and not malaria. The practice of early blood examination would in practically all cases differentiate severe untreated malaria from typhoid fever.

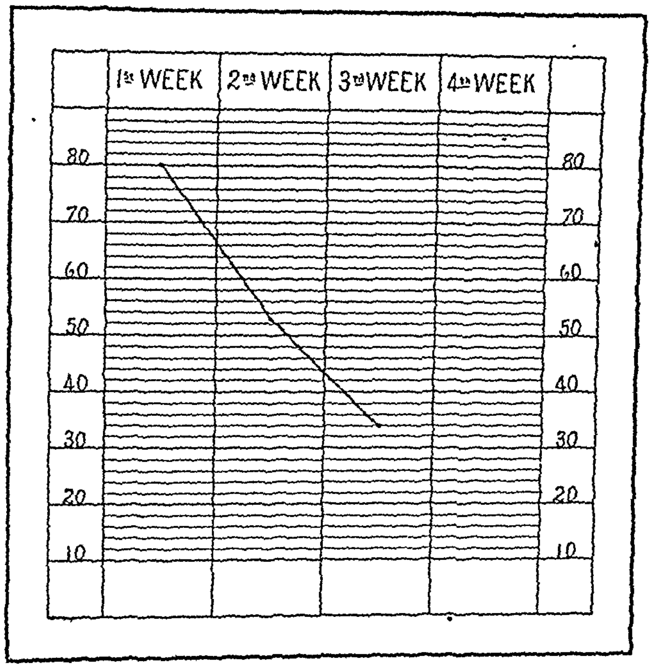

Chart 3.—Percentage line illustrating the rapid decline of positive blood-cultures during the first three weeks of typhoid fever.

Disseminated or miliary tuberculosis, in which focal physical signs are wanting, has been our greatest source of error in differential diagnosis. In not a few cases the tuberculous patient had to be treated as a typhoid-fever patient until the duration of the fever excluded typhoid. The Widal test is deceptive, and was positive in 22 per cent. of these cases as previously mentioned. A reliable clinical or laboratory finding early in the disease is much needed in these cases. Physically one of our best differential signs, when present early, has been pleural or pericardial friction. This is as common in tuberculosis as it is rare in uncomplicated typhoid fever. Early in the disease, a rapid pulse and lingual cyanosis are in favor of tuberculosis. The value of other signs in differential diagnosis so often given seems to have been over estimated so far as our negro patients are concerned. Later signs in an undifferentiated infection, as for instance intestinal hemorrhage and perforation peritonitis, are, of course, strongly in favor of typhoid fever.

"Acute infections of undetermined origin" are occasionally encountered. They commonly prove rapidly fatal. There is usually leukopenia, as in typhoid. Antemortem blood-cultures are sterile. Clinically they cannot be differentiated from grave *B. typhosus* infections. The pathologic findings exclude typhoid, show evidence of an acute infection, but shed no light on the etiology of the disease. All post-mortem cultures remain sterile.

### TREATMENT

The treatment employed in our typhoid-fever cases has been very simple and of the expectant type. The patient is usually fed exclusively on milk and broth during the fever stage. In occasional cases the patients have had oatmeal jelly, custards and orange juice added. The existing rule barring foodstuffs brought by visiting friends and relatives cannot always be strictly enforced. Hydrotherapathically, sponge baths of tap water (of about 75 F.) are given every four hours while the temperature remains over 102.5 F. Diarrhea being seldom present called for no special treatment. For constipation soap-suds enemas containing 30 minims to 1 dram of spirits of turpentine are used. During convalescence these enemas are replaced by oleum ricini in 1-ounce doses. Throughout the entire course of the disease and during convalescence phenyl salicylate (salol) in 10-grain doses is given three times daily. If stimulants are called for, strychnin and spiritus frumenti are usually preferred. During convalescence the patients are gradually returned to full diet on about the tenth day of normal temperature. All recognized antiseptic measures are of course carried out and the patient is not discharged from quarantine until two consecutive stool and urine specimens at an interval of five days are negative for *B. typhosus*. These specimens are not examined until temperature has remained normal.

### COMPLICATIONS AND THEIR TREATMENT

The following have been the complications of typhoid fever per se, in order of their frequency: phlebitis and thrombosis, 11; intestinal hemorrhage, 5; parotitis, 4; perforation peritonitis, 3; cholecystitis and periostitis, each 2; myositis and laryngitis, each 1.

The treatment of phlebitis and thrombosis was elevation of the affected limb and local application of ice. Intestinal hemorrhage was treated with morphin and ice-packs. Cholecystitis and parotitis were likewise treated with local applications of cold. One of the three cases of perforation peritonitis was recognized early enough for laparotomy and repair. All three cases proved fatal. The remaining patients who had complications, recovered spontaneously.

Complicating diseases present in their order of frequency were: estivo-autumnal malaria, 21; tertian malaria, 6; lobar pneumonia, 5; entamebic dysentery, 2; acute follicular tonsillitis, plastic pleurisy, rubeola, myringitis, gonorrheal arthritis, decubitus and sciatica, each 1. These cases were all treated in the recognized manner, irrespective of the typhoid infection. The two entamebic dysentery cases were treated by the bismuth method without any deleterious effect on the typhoid course.

### MORTALITY

In the series of 195 cases there were seventeen deaths, a mortality of 8.7 per cent. The necropsies were performed by Dr. H. C. Clark. Complications found at necropsy in addition to the usual typhoid lesions were perforation peritonitis three times, lobar pneumonia and venous thrombosis each once.

### CONCLUSIONS

Typhoid fever in the Canal Zone tropical native pursues the same variable course as in the temperate zones.

The only absolute diagnosis of typhoid fever is a positive blood-culture. The earlier in the disease that the blood is cultured, the greater the chance of making a positive diagnosis.

The Widal test has been positive in 89 per cent. during the second and third weeks. At the same time the test has also been positive in 22 per cent. of our advanced tuberculosis cases and in 15 per cent. in non-tuberculous cases of various diseases. The value of the test seems to depend entirely on its repeated application in selected cases.

The white blood-count is of great value in the diagnosis of typhoid fever. During the fever a change from leukopenia or normal to leukocytosis invariably points to complication.

Splenic enlargement in the tropics is of practically no value in the diagnosis of typhoid fever, unless previous or coexisting malarial infection can be definitely excluded.

In the differential diagnosis of typhoid fever, disseminated or acute miliary tuberculosis and "acute infections of undetermined origin" present the greatest difficulty and should always be kept in mind in the presence of leukopenia and repeatedly negative blood-cultures.

The most frequent complication of typhoid fever in the Canal Zone is malaria.

To prevent the discharge of typhoid-carriers, routine stool and urine examinations of convalescents are necessary.

## AN IMPROVED CLINICAL AND A MICROCHEMICAL TEST FOR BLOOD [*]

WILLIAM A. GROAT, B.S., M.D.
SYRACUSE, N. Y.

Small particles which look like blood or blood-tinged mucus are sometimes found in microscopic examinations of feces and similar substances, and in medicolegal examinations microscopically identified particles and dust like scrapings of minute volume require microchemical methods for fuller proof of hemic origin.

The microchemical method to be described depends on an improved benzidin test for occult blood in feces and material of this kind, and this test will therefore be described first.

Five c.c. of chemically pure glacial acetic acid is placed in each of two new or very clean 10 or 15 c.c. test-tubes and to each is added with a glass or horn spatula a knife-pointful of benzidin and an equal amount of barium dioxid. These should partly dissolve with mild effervescence, leaving a brown-straw or slightly greenish-straw supernatant fluid. If a green color develops the acid is likely contaminated with iron or the utensils are not clean, and the test should not proceed. To one of the tubes is added not to exceed 1 c.c. of the solution or extract, or a decoction of the solid material to be tested, previously boiled if ferments could be present, and at once, or within a few seconds, a deep blue or green color develops. The control tube must have held its color with no change to green or blue.

This test is so extremely delicate that it must be used with caution. The barium dioxid liberates hydrogen peroxid in the presence of the glacial acetic acid, giving more available dioxid than can be obtained by adding the official solution. Furthermore, since it does not dilute the acetic acid, the reaction is greatly sharpened and it is stable and always active, while an opened vial of $H_2O_2$, U. S. P., deteriorates.

For the microchemical test the dry material is crushed on a slide beneath a cover-slip and examined microscopically and identified if possible. A few drops of the clear portion of the reagent described is then run under the cover-slip and macroscopic blue halos quickly surround the blood-particles, or can be seen with a low power and low illumination. With moist preparations the reagent can be run under, using bibulous paper on the farther side of the cover-slip. Dry preparations may be first moistened with distilled water, salt solution, etc., as required. All utensils and reagents must be clean and pure, avoiding contamination with iron or the use of iron spatulas. Emphasis must be placed on the preliminary microscopic examination and the careful watching of those particles which have been microscopically identified as the reagent reaches them. For example, a speck of dried blood can be differentiated from a speck of iron oxid with the low power, but each will have a halo with the reagent.

600 East Genesee Street.

## A UNIQUE CASE OF VICARIOUS MENSTRUATION

D. H. GALLOWAY, M.D., ROSWELL, N. MEX.

About six years ago I was called to see a young woman who was suffering from an ulcer on each leg. Each ulcer was larger than a man's hand, not deep but excessively painful, and bled profusely. The edges were irregular in outline, not much inflamed and not raised. The legs were not swollen. For four years, despite various forms of treatment, these ulcers persisted in varying size, becoming especially large at the menstrual periods. I first tried irrigation of the ulcers with warm physiologic salt solution, several times daily, in the intervals covering them with a wet dressing of boric acid. The boric acid caused so much pain that a wet dressing of salt solution was substituted. In five or six days the ulcers were the size of a silver dollar, and ten days later one was closed, with a smooth, apparently thin skin, unlike an ordinary scar. One week afterward I found the patient suffering great pain, and the ulcers again rapidly spreading. In three days one leg was completely, the other almost, girdled. They were so painful that the patient could obtain little rest or sleep for three or four days. After several months I recommended a careful examination under an anesthetic at a hospital. About one week before the expected menstrual period, when the ulcers were most active, the examination was made.

The uterus was very small, in fact, almost infantile. The os was dilated and a cavity 1 inch deep was found. A curet passed rather vigorously over the interior produced nothing, although bleeding was rather free. I swabbed the cavity with tincture of iodin and packed the os tightly with gauze, which was removed after twenty-four hours. The menstrual flow had not previously amounted to more than a *teaspoonful*. At the time of the next period the ulcers enlarged somewhat, while the menstrual flow was largely increased. The ulcers healed in one week and so remained during the next period, although pain in the legs was complained of and the opening of the ulcers seemed imminent. They remained closed through the next month. The next menstruation was also more profuse, and the ulcers, while open, were very small.

This trouble had existed during five years, when the patient married. I predicted that pregnancy would result in a cure. She became pregnant, had slight trouble during pregnancy, gave birth to a healthy child, and since has been entirely normal.

The conclusion is unavoidable that this was a case of vicarious menstruation, though I have never read of a similar case in medical literature. In all other reported cases the vicarious flow has been through some natural orifice, the rectum, the nose, the mouth, the eyes or the nipples. I believe that this case is unique.

## AN UNUSUAL ANOMALY OF THE LEFT PULMONARY VEIN

James Patterson, M.D., Chicago

Notable anastomoses between pulmonary and systemic venous systems are so rare as to deserve mention. In this subject, dissected in the anatomic laboratory of the University of Chicago, a large vein draining the upper two-thirds of the left lung coursed upward and emptied into the vena anonyma sinistra about 1.5 cm. from its beginning at the junction of the vena jugularis interna with the vena subclavia. About 5 cm. from its mouth this vena pulmonalis aberrans gave off a branch which ran posteriorly over the median surface of the lung and emptied into the vena hemiazygos accessoria. On dissecting out the radicals of this unusual vessel it was found that all the blood returning from the upper lobe and the upper half of the lower lobe of the left lung was short-circuited. A relatively small vein from the lower part of the lung entered the left atrium in the normal way.

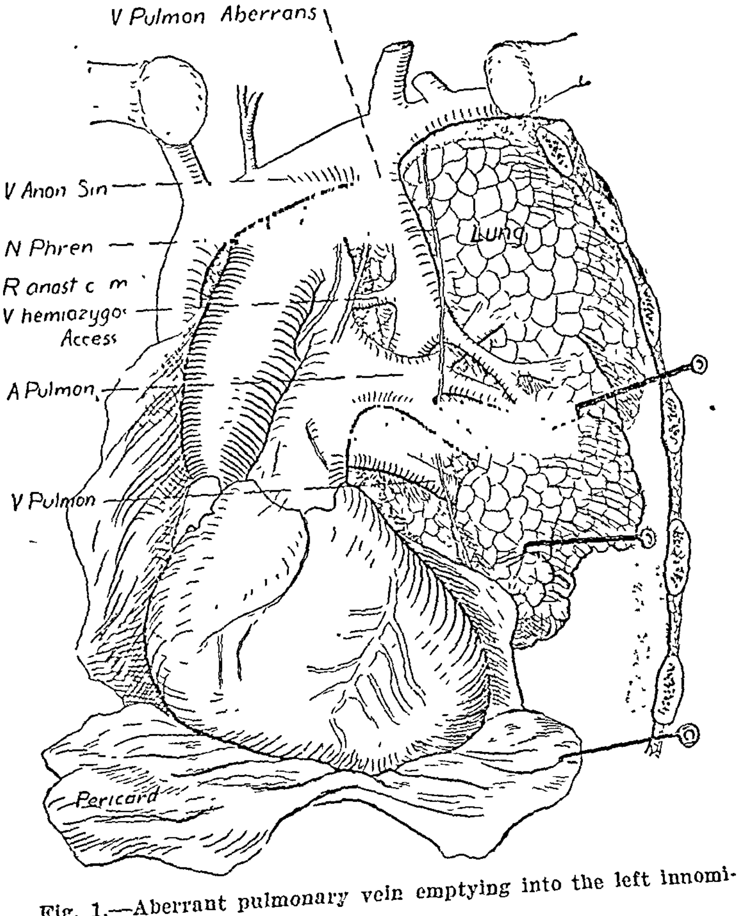

Fig. 1.—Aberrant pulmonary vein emptying into the left innominate vein.

A number of uncommon connections have been described before. Piersol[1] and Quain[2] in their texts mention that a connection similar to the one before noted has occurred and they also say that the upper pulmonary vein on the right side has been seen opening into the vena azygos major. Looten and Ruyssen[3] depict a vein from the upper third of the left lung emptying into the left innominate. They cite Meckel and Gegenbaur, and Grüber as describing two cases of the right superior pulmonary vein going into the superior vena cava; Weber as finding a connection between the left pulmonary vein and the left subclavian, and Bachmann as showing a left pulmonary vein emptying into the left innominate. The azygos has also been found an unusual tributary to the innominate. So far as I have been able to find them, there are only two cases on record of the aberrant pulmonary vein connecting with the innominate, that of Bachmann and that noted by Looten and Ruyssen, and in these cases there was not found the auxiliary anastomosis with the hemiazygos accessoria which is shown in the accompanying illustrations. The rarity of the anomaly is the reason for putting it on record.

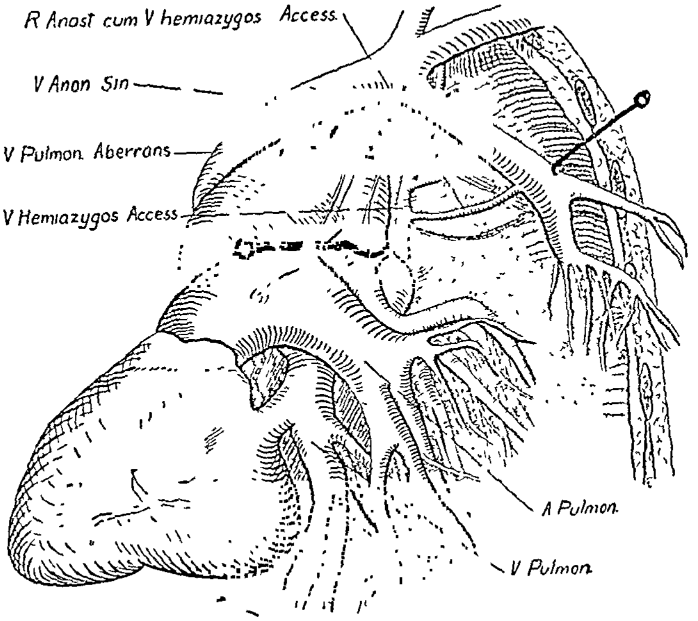

Fig. 2.—Dissection illustrating smaller branches.

I am indebted to Dr. J. H. Mitchell and Mr. A. B. Streedain for the drawings.

## RUPTURE OF THE SIGMOID BY AN AIR-BLAST OF 120 POUNDS PRESSURE

Harlan Shoemaker, A.B., M.D., Shelby, N. C.
Surgeon of the Shelby Hospital

On May 8, 1913, a mill-boy sneaked behind the patient and played an air-hose on the rectum as he was leaning over his "doffer's box." The injured boy dropped at once and lost consciousness immediately. The air-blast was 120 pounds pressure to the square inch. Dr. W. H. Hauser of Cherryville called me into consultation the next day. The patient was moved to the hospital twenty hours after the accident. At the consultation and on admission his abdomen was distended and tender, with some rigidity of the muscles. No blood was passed by the rectum. He vomited food and nourishment. A rapid hard pulse (120) of small volume and a temperature of 100 degrees was noted.

---

1. Piersol: Human Anatomy, Vol. i, pp. 854-858, 859.
2. Quain: Anatomy, Vol. ii, Part 2, p. 379.
3. Looten, J., and Ruyssen, C.: Bibliographie Anat., 1910, xx, 219.

Through a left rectus incision under chloroform, the abdominal cavity was found full of blood with a slight odor. The upper portion of the rectum and all of a very redundant sigmoid were split along the free margin of the intestine. Above the sigmoid and in the lower portion of the descending colon two transverse tears crossed the bowel. The effects of the air-blast, by the stretching and checking of the peritoneum as well as by the congestion of the blood-vessels, could be seen as far as the cecum. The small intestines were collapsed and were not congested. The tear in the intestine was not completely through it. The serous and muscular coats were torn through, but the mucous coat was stretched to the thinness of tissue-paper and filled a 10-inch gap.

The mucosa was folded in by interrupted stitches of sea-island cotton placed in the muscular and serous layers of the bowel. A double row of stitches was used throughout. The intestine was opened well above the traumatic area of the bowel in the descending colon. A No. 24 French catheter was passed out of the rectum and fastened in the bowel by one stitch of chromic catgut. The bowel was closed by interrupted stitches of sea-island cotton and a drain was placed in the pelvis. The patient made an uneventful recovery.

In the postoperative treatment the head of the bed was slightly elevated and gas was expelled through the tube in thirty-six hours, when water by the mouth was begun and retained without distention. The pelvic drain was removed in one week and the rectal tube was expelled at the same time. The patient was nourished on liquids for fourteen days and at the end of that time the bowel movements became normal with the aid of an ounce of glycerin injected high up in the sigmoid through a small catheter. No medicine, opiates or purgatives were used by mouth or by hypodermic injection. By palpation the condition of the sigmoid could be judged at all times, and the tube in the intestine drained off the gas and some fecal matter continuously. I made no attempt to rush fecal matter over a very much sewn intestine; consequently, the stretched mucosa of the sigmoid did not slough.

---

## A CASE OF AMEBIC DYSENTERY TREATED WITH EMETIN HYDROCHLORID

R. E. Cloud, M.D., Ensley, Ala.

*History.*—S. J. G., aged 34, white, male, was born in Kentucky and moved at the age of 17 to Decatur, Ala., where he lived about ten years. From Decatur he came to Birmingham (Ensley), which has been his residence continuously for the past seven years. Eight years ago he spent a month in Houston, Tex., which single trip constitutes the extent of his travels.

The present trouble began three and a half or four years ago with frequent movements of bowels (fifteen or twenty stools in twenty-four hours), straining, pain in hypogastrium and over sacrum and tenderness in epigastrium. Movements consisted mostly of blood and mucus. Attacks of this kind, more or less severe, recurred three or four times a year, usually lasting a month or more. Stools would number two or three a day during intervals between severe attacks, never being entirely free from mucus and blood and practically all accompanied by tenesmus.

At the time that the patient consulted me, September 15, he was suffering with a moderately severe attack which had developed four or five days previous and just reached the point where he had to discontinue work.

*Physical Examination.*—Height 5 feet 8½ inches, weight 140 pounds (formerly his weight averaged about 160). No evidence found of pathologic condition in thorax. Tenderness in epigastrium and hypogastrium. Stool (passed in a vessel in my office), macroscopically, seemed to consist of only blood and mucus; microscopically, motile amebas were found in the first field.

*Treatment and Results.*—September 15 the patient had six or eight movements from early morning to noon. Milk diet was prescribed and ½ grain emetin hydrochlorid given hypodermatically.

September 16. Four stools since the day before; a little blood in the first two, mucus in all. Emetin 1 grain.

September 17. Three stools in last twenty-four hours but no red blood in any. General appearance yellow with some mucus. Emetin 1 grain.

September 18. Two well-formed yellow movements, a little mucus, no blood. No emetin given; supply exhausted.

September 19. One stool about 11 a. m., yellow and perfectly normal in appearance. Patient says that this is the first morning that he has not been forced to go to the toilet, immediately on rising in probably a year. No pain or straining and only slight tenderness in epigastrium. A final dose of 1½ grains emetin was given, although the case, clinically, seemed cured.

September 24. Returned to work on Monday, September 22; all symptoms absent since the 18th and only one movement per day since that date. Feels "remarkably" well. Stool perfectly normal in appearance, well formed, no suggestion of blood or mucus.

All treatments were given in my office. There was not the least nausea or, in fact, any noticeable constitutional effect following injections although patient had to go home on the car (about a mile) after each dose.

After the second day soft diet was allowed and on the fifth patient was told to eat whatever he desired.

1903½ Avenue E.

## A SIMPLE AND PRACTICAL METHOD FOR THE PREPARATION OF PURE BUTTERMILK

Sverre Oftedal, M.D., Climax, Minn.

The rôle of buttermilk, particularly in the artificial feeding of infants and in the treatment of gastro-intestinal disorders of the first two years of life, has made its use a matter of necessity among rich and poor alike. A practical method for its preparation seems, therefore, to be a matter of considerable importance.

This idea was suggested through a study of the recent work of Clock and others along the lines of the lactic acid bacillus principle of treatment, and its use is largely based on the administration of the culture of the *Bacillus lactis bulgaricus*, Type A (Grigoroff), although its preparation is not necessarily dependent on this form of lactic acid bacillus culture preparation.

There are two methods for the preparation of buttermilk according to this principle, the choice of which would depend on whether the physician or trained nurse is able to carry out the work in person, or must leave it to the mother or some one else in charge who has no knowledge of bacteriologic or dietetic principles:

1. In carrying out this method I have obtained the kind assistance and cooperation of the buttermaker in charge of a local creamery. It is a well-known fact that the buttermaker uses a pure culture of lactic acid bacillus in the process of "ripening" the cream. This culture is kept fresh by frequent renewal or "propagation." The mother or nurse is instructed to obtain a small amount of this culture in a bottle or hermetically sealed jar, which has previously been placed in boiling water for a few minutes and then corked or sealed. This must, of course, be kept in a cool place at the home. A pint of whole or skimmed milk, as the case may indicate, is placed in a boiler, preferably a double boiler, brought to a boiling point over a slow fire and then cooled down to room temperature without the lid of the boiler being removed. A teaspoonful of the culture (the spoon which is used having been held in boiling water for a minute or two) is then put into the milk and the whole allowed to stand at room temperature for eight hours, after which it is cooled down and kept ready for use. This method may be carried out in any household which has access to a creamery. It has been my experience that the buttermaker is very willing to cooperate with the physician in the work, and some remuneration may easily be arranged for.

2. This method requires a little *more scientific* detail, and is best carried out by the physician or trained nurse in person. Whole milk is cooled down to about 50 F. immediately after milking by the vessel being immersed in ice-water. It is then pasteurized at 180 F. for thirty minutes. After cooling down to 80 F. implantation is carried out by the use of the tablets of *B. lactis bulgaricus*, Type A (Grigoroff), in the proportion of six tablets to a half pint of milk. It is kept at this temperature for eight hours, or until the milk is coagulated. If used before coagulation has taken place it will have a bitter, disagreeable taste. After coagulation, however, it assumes a very agreeable odor and taste. The culture, after being thus prepared, may be further propagated, according to the first method, by simple transplantation every twenty-four hours, and an indefinite amount of buttermilk be thus prepared. A culture may be safely carried along for two weeks, when a fresh culture should be prepared.

# *New and Nonofficial Remedies*

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED BY THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION. THEIR ACCEPTANCE HAS BEEN BASED LARGELY ON EVIDENCE SUPPLIED BY THE MANUFACTURER OR HIS AGENT AND IN PART ON INVESTIGATION MADE BY OR UNDER THE DIRECTION OF THE COUNCIL. CRITICISMS AND CORRECTIONS ARE ASKED FOR TO AID IN THE REVISION OF THE MATTER BEFORE PUBLICATION IN THE BOOK "NEW AND NONOFFICIAL REMEDIES."

THE COUNCIL DESIRES PHYSICIANS TO UNDERSTAND THAT THE ACCEPTANCE OF AN ARTICLE DOES NOT NECESSARILY MEAN A RECOMMENDATION, BUT THAT, SO FAR AS KNOWN, IT COMPLIES WITH THE RULES ADOPTED BY THE COUNCIL.

W. A. PUCKNER, SECRETARY.

**ACNE VACCINE.**—(See N. N. R., 1913, p. 221.)

The Abbott Laboratories (The Abbott Alkaloidal Co.), Chicago.

*Acne-Bacterin Polyvalent.*—Marketed in four syringes containing respectively 25 million, 50 million, 100 million and 200 million killed Bacillus Acne.

**BACILLUS COLI VACCINE.**—(See N. N. R., 1913, p. 221.)

The Abbott Laboratories (The Abbott Alkaloidal Co.), Chicago.

*Coli-Bacterin Polyvalent.*—Marketed in four syringes containing respectively 50 million, 100 million, 200 million and 400 million killed Bacillus Coli Communis.

**FRIEDLAENDER VACCINE.**—(See N. N. R., 1913, p. 222.)

The Abbott Laboratories (The Abbott Alkaloidal Co.), Chicago.

*Friedlander Bacterin Polyvalent.*—Marketed in four syringes containing respectively 50 million, 100 million, 200 million and 400 million killed Friedlander bacilli.

**GONOCOCCUS VACCINE.**—(See N. N. R., 1913, p. 223.)

The Abbott Laboratories (The Abbott Alkaloidal Co.), Chicago.

*Gonococcus-Bacterin Polyvalent.*—Marketed in four syringes containing respectively 50 million, 100 million, 200 million and 400 million killed Gonococci.

**PNEUMOCOCCUS VACCINE.**—(See N. N. R., 1913, p. 224.)

The Abbott Laboratories (The Abbott Alkaloidal Co.), Chicago.

*Pneumo-Bacterin Polyvalent.*—Marketed in four syringes containing respectively 50 million, 100 million, 200 million and 400 million killed Pneumococci.

**MIXED VACCINES.**—(See N. N. R., 1913, p. 224.)

The Abbott Laboratories (The Abbott Alkaloidal Co.), Chicago.

*Staphylo-Acne-Bacterin Polyvalent.*—Marketed in four syringes. Syringe 1 contains 250 million mixed Staphylococci and 25 million Acne Bacilli. Total 275 million killed bacteria. Syringe 2 contains 500 million mixed Staphylococci and 50 million Acne Bacilli. Total 550 million killed bacteria. Syringe 3 contains 1,000 million mixed Staphylococci, and 100 million Acne Bacilli. Total 1,100 million killed bacteria. Syringe 4 contains 2,000 million mixed Staphylococci and 200 million Acne Bacilli. Total 2,200 million killed bacteria.

**STAPHYLOCOCCUS VACCINES.**—(See N. N. R., 1913, p. 225.)

The Abbott Laboratories (The Abbott Alkaloidal Co.). Chicago.

*Staphylo-Albus-Bacterin Polyvalent.*—Marketed in four syringes, containing respectively 200 million, 400 million, 800 million and 1,000 million killed Staphylococcus Albus.

*Staphylo-Aureus-Bacterin Polyvalent.*—Marketed in four syringes containing respectively 200 million, 400 million, 800 million and 1,000 million killed Staphylococcus Aureus.

*Staphylo-Bacterins (Human) Albus-Aureus-Citreus.*—Marketed in four syringes containing respectively 200 million, 400 million, 800 million and 1,000 million killed bacteria.

**STREPTOCOCCUS VACCINE.**—(See N. N. R., 1913, p. 226.)

The Abbott Laboratories (The Abbott Alkaloidal Co.). Chicago.

*Strepto-Bacterin (Scarlatina Bacterin) Polyvalent.*—Marketed in four syringes containing respectively 50 million, 100 million, 200 million and 400 million killed streptococci from scarlet fever cases.

*Antistreptococcic Vaccine (Scarlatina Prophylactic).*—Marketed in packages of three syringes containing respectively 250 million, 500 million and 1,000 million killed streptococci from scarlet fever cases.

*Strepto-Bacterin (Human) Polyvalent.*—Marketed in four syringes containing respectively 50 million, 100 million, 200 million and 400 million killed streptococci.

**TYPHOID VACCINE.**—(See N. N. R., 1913, p. 227.)

The Abbott Laboratories (The Abbott Alkaloidal Co.), Chicago.

*Typho-Bacterin Polyvalent.*—Marketed in four syringes containing respectively 100 million, 200 million, 400 million and 800 million killed Typhoid Bacilli.

*Typhoid Prophylactic.*—Marketed in packages containing three syringes, containing respectively 500 million, 1,000 million and 1,000 million killed bacteria.

**ARHEOL.**—Arheol is santalol, $C_{15}H_{26}OH$, a sesquiterpenic alcohol, the chief constituent of sandalwood.

*Actions and Uses:* The action of arheol is the same as that of sandalwood oil. It is claimed that because of its purity it does not occasion disturbance of the stomach or the kidney. It is asserted to be useful in urethritis, cystitis and vesical catarrh, especially from gonorrhea.

*Dosage:* 0.40 to 0.60 gm. (6 to 9 grains). Arheol is marketed only in capsules containing 0.20 Gm. (3 grains) of which 9 to 12 capsules are to be taken daily.

Manufactured by Alexander Astier, Paris, France. No U. S. patent. U. S. trademark No. 72,513.

*Arheol Capsules.*—Each capsule contains Arheol 0.2 Gm. (3 grains).

Arheol is a colorless, oily liquid; specific gravity, 0.979 at 15 C. It is insoluble in water but soluble in alcohol. It boils under 11 mm. pressure at 169 degrees, and under ordinary pressure at about 500 C.

# *Therapeutics*

## PUERPERAL INFECTION

This discussion does not aim to be dogmatic, but suggestive. Though septic infection after parturition occurs much less often than even a few years ago, it is still sufficiently frequent to necessitate resort to every possible method of prevention and to the thorough consideration of effective but non-meddlesome treatment.

This infection occurs most frequently in one of two general forms. One is a typical blood-poisoning or sapremia, which is caused by the absorption of toxins or decomposition products of substances that are undergoing putrefactive or other chemical changes in the genital tract. Of course the most frequent substances causing such poisoning are retained fragments of the placenta or membranes, or, if there is any obstruction to the exit of the normal lochia, there may be absorption from this

Such poisoning may be termed an auto-intoxication or autotoxemia. This poisoning may cause more or less rise of temperature, but it may not be high, and although an increased temperature in the first few days after parturition may be due to a bowel infection, to the absorption of bowel toxins, to some disturbance of the mammary glands, to some bladder or kidney disturbance or, of course, to some acute infection to which the patient may have been exposed, still, generally, the cause of such fever will be found to be in the genito-urinary tract. Slight injuries of the uterus, vagina or perineum during parturition may allow absorption of and poisoning by discharges that would otherwise be innocuous.

The other more serious cause of puerperal infection or puerperal fever is the absorption and circulation of pathogenic bacteria. Of these may be mentioned some varieties of streptococcus, pneumococcus, staphylococcus, gonococcus, and perhaps not infrequently the colon bacillus. Localized infections and more or less general disturbance from the last three of these pathogenic germs may not be serious infections as far as the immediate consequences are concerned and perhaps could hardly be called septic fever. Infections, however, from some form of streptococcus and occasionally from the pneumococcus are always serious; the patient is septic and is suffering from dangerous septicemia. A puerperal streptococcic infection quite commonly, though not always, will show a bacteriemia and may have as a complication endocarditis, even the malignant type, with perhaps associated local lesions such as pneumonias, pleurisy and kidney infection, a pyelitis or a localized septic process in the kidney substance. Such a general infection is usually associated with more or less pelvic inflammation and pelvic tenderness, but is commonly without any pelvic abscess or purulent discharge.

It can easily be understood how a slight injury or even a denuded surface of mucous membrane in the genital tract, consequent on parturition, with its surrounding vascular supply normally increased and lymphatic supply perhaps increased owing to the needs of the previous pregnancy, gives such a dangerous possibility and almost a probability of the absorption of poisons and germs. A certain amount of abnormal absorption generally occurs, but is combatted by the normal woman. Such small absorptions are probably the cause of the frequent slight rises of temperature which last for a few hours or a day and then disappear, representing the normal neutralization of such toxins or the normal rendering inert of such germs. In other words, the resistance of the patient has proved entirely sufficient to combat the infection.

If we accept the wound or abrasion theory of most puerperal infections the poison is really external to the body and is absorbed, unless there is some previously localized infection, such as that from a gonococcus. Consequently, the prevention of infection before, during and subsequent to a parturition, proper cleanliness and care of the patient without meddlesome and obstructive treatment or methods of treatment, and without removing Nature's own protective secretions, are the objects at which to aim.

### PREVENTION OF INFECTION

Most of the preventive measures are too well understood to require more than enumeration. The selection and preparation of the room, the preparation of the patient and of himself are well-understood duties of the attending physician. The nurse also well understands the preparation of herself. A few details, however, should be emphasized. The nose of the patient should be gently sprayed and cleansed with an alkaline or mild antiseptic solution. The mouth and throat should be washed with some mild antiseptic mouth-wash, and the teeth thoroughly cleansed. The nurse should not give the patient a vaginal douche unless ordered to do so by the physician. The nurse should be free from any purulent discharge, especially from the nose, throat or even ears. She cannot be too careful in observing the greatest possible cleanliness in the care of the vulva and the vaginal discharges, with the use of such antiseptic solutions and gauze as the physician directs. If the patient must be catheterized, too great care cannot be taken to prevent infection of the bladder.

Although a physician may take every means possible for personal disinfection and wear a sterilized gown and rubber gloves, it seems, except in isolated instances, unjustifiable for him to accept a case of obstetrics while he is in attendance in a case in which there is contagion, or immediately subsequent to handling such a case, whether it be of scarlet fever, erysipelas, measles or diphtheria. After having cared for a patient with puerperal fever, he should not accept another case of obstetrics for some time and he should not attend a case of obstetrics while he is caring for any septic patient.

The patient ordinarily should not be given a vaginal douche just before parturition. Very frequently one vaginal examination by the physician, to determine the exact position of the child and the condition of the os uteri, is all that is needed. This examination should be made after sterilization of the hands and with the use of rubber gloves. When there is any delay in a normal labor, any apparent malposition, or other complicating disturbance, several vaginal examinations must be made. Of course in all operative interference manipulations are more or less necessary, and although the instruments may have been properly sterilized, injuries to the parts are very likely to occur and the danger of future infection is much greater.

If there is any purulent catarrh of the vagina, especially if gonorrhea is present, cleansing and perhaps mildly antiseptic douches should generally be used. On the other hand, with a normal vagina it seems unwise to remove the secretions which facilitate the expulsion of the child and at the same time protect the mucous membrane.

There is a difference of opinion as to the proper management when portions of membrane or of the placenta are found by examination of the expelled after-birth to have been retained. Some obstetricians would leave these retained substances to be loosened and expelled by natural processes, when ordinary gentle manipulation of the uterus does not expel them. Others believe that the sterilized, rubber-gloved hand should gently clean the vagina, and, if necessary, the uterus. The removal of retained portions of the placenta may prevent unpleasant and even dangerous hemorrhage.

The routine administration of fluidextract of ergot three or four times daily for several days after parturition in 1 c.c. (15 minim) doses, is believed by some modern obstetricians to aid and hasten involution of the uterus. If for any reason ergot is not tolerated or is inadvisable, quinin in 0.2 gm. (3 grain) doses twice a day may be of benefit in furthering this object. Just what usage of pituitary extracts is safe has not yet been clinically determined

## THE VENTILATION PROBLEM

It is a commonplace that "bad ventilation" and close rooms produce discomfort and more or less injurious consequences to the persons subjected to their influence. The inquiring mind at once asks two questions, related but distinct: 1. To what external factors is this effect due? 2. What are the physiologic changes in the human organism to which these factors give rise? In what does poor ventilation consist and how does poor ventilation affect the human body?

The first question has been answered variously at different stages in the progress of scientific investigation. An early and natural explanation of the ill effects observed in indoor crowding was that either the decrease of oxygen or the increase of carbon dioxid in respired air or both were responsible for the physiologic mischief. It was soon found, however, that the oxygen content of air could be reduced far below that noted in very badly ventilated rooms, and that carbon dioxid could be increased far beyond the amount ordinarily observed under the worst conditions of crowding without producing any of the usual physiologic consequences of bad ventilation. The air of a brewery may contain ten times as much carbon dioxid as that of a very poorly ventilated room, and yet men may work in such an atmosphere for years without any ill effects. Again, lack of oxygen, barring such extreme cases as the famous Black Hole of Calcutta and the ship *Londonderry* with its battened-down hatches, can hardly be a factor in ordinary conditions of ventilation, since there is less oxygen in a given quantity of the air of famous mountain health resorts than in the air of the most crowded room at lower levels. Experimentally, it has been demonstrated repeatedly that neither insufficiency of oxygen nor excess of carbon dioxid can account for the sensation of discomfort experienced in a "close" room.

It was next believed for a time that some organic poison in expired air was at the bottom of the trouble, and most of the "standards" of ventilation long in vogue were drawn up on the assumption that carbon dioxid, although not itself harmful in the proportion that obtained in rooms inhabited by human beings, was nevertheless an index of the organic impurity of the air. Early experiments seemed to give some support to the doctrine of the toxicity of expired air, but the results of these tests were shown later to rest on experimental error, and numberless recent experiments have failed to yield any basis for believing in the presence of a poisonous substance in the breath. This plainly does not mean that the chemical changes in rebreathed air are of no physiologic significance, but simply that there is thus far no evidence that they are the source of the trouble. During the last few years attention has been focused especially on the physical conditions in the air of crowded rooms. The investigations of Flügge, Leonard Hill, Hough, Benedict and Milner and others have emphasized the physiologic importance of high temperature, moisture content and air stagnation in their bearing on the ventilation problem. All these experiments agree in placing the responsibility for the observed physiologic effects on these physical factors. Certainly so far as the available evidence goes, these factors are adequate to explain all we know about the influences of good and bad ventilation. Hill has recently declared that he is "convinced that the whole of the effect of open-air treatment is due to the movement, temperature and moisture of the air, and has nothing to do with its chemical properties." It is a cardinal principle in science that when given effects are satisfactorily explained by a given set of causes it is not desirable to summon in mysterious and unknown agencies to help in explaining something already adequately accounted for. It may be true that other influences than the physical ones mentioned are concerned in the ventilation problem, but at present and until positive evidence is available it is more practical as well as more scientific to deal with the demonstrated and the tangible rather than invoke the existence of unknown and undemonstrable "possibilities."

We cannot at present do more than touch on the way in which these physical factors affect the physiologic mechanism of the human body. Whether by interfering with the heat-eliminating function of the skin as maintained by Flügge, Hill and others, or by inhibiting the process of oxygen secretion in the lungs, as recently suggested by Henderson,[1] warm, moist, stagnant air does in some way prevent the human machine from doing its work properly. The matter of adjustment to changed physical conditions is probably a complex one as shown by the phenomena of adaptation to life at high altitudes, and there are doubtless important differences in individuals that will have to be taken into account in experimental work, but already the analysis of the physiologic reactions to changes in indoor climate seems well under way.

Practically there is still much to learn about ventilation in the actual control of temperature, humidity and air movement. Little or nothing is yet known, for example, about the degree of humidity most favorable to physiologic well-being under ordinary working conditions. Extensive experiments on a sufficiently large number of persons will undoubtedly throw light on this and other obscure points. The ventilation commission appointed by the state of New York and provided with ample funds has an unrivaled opportunity to solve this and kindred problems.

---

[1] Tr. Fifteenth Internat. Cong. Hyg. and Demog., 1913, ii, 62

Finally, it may be pointed out that all the discussion and investigation of the factors concerned in ventilation and of the precise nature of the physiologic response does not affect the necessity for good ventilation. Fresh, cool, moving air is just as good as it ever was for the human organism, whether we believe that its virtue is due to the fact that it contains no "toxic substance," or simply that it is fresh and cool and moving. The bad effect of close, stuffy rooms and the good effect of the open air are facts, no matter how we explain these influences or what measures may be found best for meeting the problem of practical ventilation.

## A HUMAN BEING WITHOUT CEREBRAL HEMISPHERES

The classic experiment of Goltz[1] in which he removed both cerebral hemispheres from a full-grown dog which was subsequently kept alive for some years has since been duplicated by others and has furnished the basis for important deductions regarding the functions of the portions of the brain involved. In a decerebrate dog it is evident that all those reactions in which the associative memory plays a part are permanently lacking, while the simple reactions that depend on inherited conditions only, may remain. In accordance with this the dog without cerebral hemispheres sleeps and wakes; it moves spontaneously; there is an extreme restlessness doubtless connected with the removal of cerebral inhibitions. Discrimination is shown by such animals with respect to food of varying taste. Goltz's dog could still bark and howl. It could be awakened by noise and it responded to bright light. On the other hand, it could not seek its food and recognized neither master nor companions.

The general impression which one gathers from the investigations of cerebral functions in animals is that their subcerebral centers are complete enough to be able to carry out many motor reactions independently of the higher hemispheres of the brain. It is, of course, desirable to ascertain to what extent the facts of animal experimentation find their analogy in the workings of the human brain. Accidents have furnished numerous instances of partial loss of cerebral substance; but such cases are far from comparable with those in which there is extensive or complete removal of the hemispheres. There are instances on record of human beings born without a cerebrum, but they have been anencephalous fetuses which have survived for only a few days. Even the scanty observations made in such cases have demonstrated that in the absence of a cerebrum movements of the limbs and eyelids, sucking movements and the act of crying can be carried on successfully. It has remained for Edinger and Fischer[2] to furnish the first description of a human being devoid of cerebral hemispheres who has remained alive for any considerable period. Their subject was under observation until its fourth year, when death, due to pulmonary tuberculosis, occurred. We are told that, although the symptoms exhibited by the child gave occasion to assume the existence of some severe brain involvement, prior to the necropsy, no one would have suspected the complete absence of the cerebrum. Entirely occupying the place of this portion of the brain was found a membranous bag filled with fluid, while the lower portions of the central nervous system exhibited a fairly complete and normal structure.

The very satisfactory account of this child's experiences during the three and three-quarter years of its life which Edinger and Hirsch have fortunately succeeded in obtaining impresses one with the decided inferiority of the decerebrate human subject as contrasted with comparable dogs. The child showed scarcely any change of behavior from its birth to its death. This is not true with regard to decerebrated dogs for which suitable records have been obtained. These learned to walk, to assume characteristic postures in the acts of defecation and urination, to alternate sleep and waking. The child never acquired such capabilities. It lay motionless in sleep unless wakened, and unlike the dogs, failed to learn to take food otherwise than by the primitive act of sucking. Like the dogs, it was apparently blind. It seemed impossible to discover a reaction whereby any relation which was semipsychic or conscious on the part of the child could be entered into. To quote the German observers: The child without cerebrum was less capable than a decerebrate fish or frog.

The difference in the reactions of various animals to lesions of the motor cortex is now explained by physiologists as being connected with the gradual shifting of functions from the sphere of necessary reactions to the sphere of educatable adaptations, that is, from the lower centers to the cerebral cortex.[3] This is characteristic of the evolution of the higher type of nervous system and is a concomitant of the increased adaptability which distinguishes man from all the lower animals. In the animal without hemispheres the motor mechanisms for all the movements of the body are present and can be set into action from any point on the sensory surface of the body. The first effect of adding the cerebral hemispheres to this mechanism is to increase the range of reactions, to modify or inhibit them, by diverting the stream of nervous impulses into channels which have to a large extent been laid down in the cortex by the past experience of the individual. In the dog, although a portion of the brain is in direct connection with the spinal motor centers, and can therefore initiate movements without making use of the midbrain motor machinery, these movements play only a small part in the motor life of the animal, and the removal of the corresponding centers takes away little of the conscious functions of the animal. In man the enormous power of acquisition of new movements is, as Starling emphasizes further, rendered possible by the shifting of one motor function after another to the sphere of influence of the cerebral hemispheres. Almost every act of human life has come to involve the cooperation of the cerebral cortex. The motor defects and the lack of adaptations exemplified in the child we have described would seem to show that the subcerebral centers in man are not complete and that this lack is permanent.

## ANATOMY IN THE FAR EAST

An interesting account recently published by Dr. Elbert Clark,[1] professor of anatomy in the College of Medicine and Surgery of the University of the Philippines at Manila, indicates the pioneer work which has been done by our Bureau of Science in the Far East to foster the adequate study of the fundamental premedical science of anatomy. Probably few practitioners in the United States realize the difficulties inherent in the introduction of this subject among peoples hitherto entirely out of sympathy with the aims of modern science and even positively opposed to the innovations proposed by its teachers. Dr. Clark informs us that to the present time in China a religious respect for custom and tradition, the worship of ancestors and the great fear of arousing public disapproval have made the teaching of anatomy and pathology in the medical schools there all but impossible. Necropsies on natives are not permitted in China and the dissection of a Chinaman, particularly by a foreigner, would be sufficient grounds for a riot. Dissection and necropsy on the human subject are directly opposed to the ancient culture for which China has decidedly more respect than for that of the West. Therefore Clark believes that of all branches of western education modern anatomy and pathology will be the last to gain admission. We are told, however, that should the present form of government continue, the outlook for the study of anatomy may improve rapidly; for the medical missionaries and the Chinese educated abroad, many of them in medicine in America, have been most directly responsible for the "awakening of China," the recent revolution, and the growing popularity of western education.

Dr. Clark remarks that in China, where there is so much superstition concerning the human body—a superstition which many Chinese physicians seem never to overcome thoroughly for themselves—the teaching of dissection should be a most desirable and practical measure in medical education. He adds that a glimpse of what is inside the natural human being would, no doubt, tend to allay much of the native superstition and give the student more confidence in the foreigner's later instruction. In Hongkong the British colony has succeeded in making dissection and necropsies available to the Chinese students; and this new sort of education is said to produce good effects where, owing to a system of education so long in vogue, there is a great tendency to drift into learning anatomy by memory from books. In French Indo-China courses in medicine are given to the natives in the medical school at Hanoi. Inasmuch as the primary object of this institution seems to be to train high-class hospital assistants, quarantine assistants, sanitary inspectors, etc., to fill minor positions in the government service and it is rare to see a native graduate in practice for himself, there is no tendency to develop along higher scientific lines a subject like anatomy, which is of little direct practical value. There has been no policy such as obtains in our Philippines of placing higher education within the reach of the native.

Great as have been the advances in medicine in Japan there still exists, according to Clark, a prejudice against the free use of the human subject by the anatomist or the pathologist. Indeed one gains the impression from Dr. Clark's report that by contrast with what exists elsewhere in the Far East the American dependencies are to be congratulated on the excellent advantages which they offer for medical instruction and the good spirit which seems to actuate the students in the Philippines.

## THE HYPOTHESIS OF THE SELF-LIMITATION OF POLIOMYELITIS

Epidemic poliomyelitis does not attack all who are exposed to it, but appears to select its victims, leaving others quite unharmed. In some cases the attack is so mild as to be recognized with difficulty. What can be the reason of this apparent variation in susceptibility? Kling and Levaditi[1] have made some observations that are of much interest and significance with respect to this question. The serum of patients who are in the midst of an attack or who have passed through an attack destroys or neutralizes the poliomyelitis virus. This is demonstrated by injecting monkeys with suitable mixtures of virus and serum. Tests of this kind with the serum of young persons who appeared to be refractory to poliomyelitis because they remained perfectly well while living in the midst of a heavily infected district gave, in two out of nine experiments, complete protection, in five partial protection and in two none at all.

How are such results to be explained? One may suppose that the antibodies on which the resistance would seem to depend are the expression of a natural, inborn immunity or the result of what may be called a latent infection which does not develop to such an extent that recognizable symptoms are produced — in other words, the result of an acquired immunity due to a spontaneous protective vaccination or inoculation. The virus invading the upper respiratory passages multiplies sufficiently to produce a distinct antigenic effect, but no other appreciable reactions. Kling and Levaditi are inclined to favor the latter hypothesis, at least provisionally. In order to test the correctness of this hypothesis further, it would be necessary to repeat the experiments on the protective action of serum with the serum of individuals that have not been exposed to the virus.

---

[1] Clark, E.: Anatomy in the Far East, Anat. Rec., 1913, vii, 237.

[1] Kling and Levaditi: Ann. de l'Inst. Pasteur, 1913, xxviii, 57.

If it should be found that the serum of such individuals is quite devoid of protective action, the hypothesis in question would be strengthened very materially. If, on the other hand, such serum were found to be protective also we would have to conclude that a natural inborn immunity to poliomyelitis does exist in certain individuals. In case the former hypothesis of a latent, clinically harmless infection should be confirmed, then the idea already advanced that the virus of poliomyelitis is much more profusely disseminated than indicated by the occurrence of actual instances of the disease would be securely fortified. If so disastrous a disease as poliomyelitis limits its spread spontaneously by the creation of an active immunity in the manner hypothesized by Kling and Levaditi, it is indeed fortunate.

### THE FRIEDMANN "CURE"—FURTHER DISGRACEFUL PRESS WORK

Milwaukee is the western headquarters of the Friedmann "cure" concern. The assistant commissioner of health of that city, Dr. E. Wells Kellogg, seems to be hand-in-glove with those who are exploiting the remedy. On the other hand, the physicians of Milwaukee, practically as a unit, condemn the Friedmann business, and some time ago the Medical Society of Milwaukee County passed resolutions making clear its stand in the matter.

On November 14, Dr. E. Wells Kellogg presented a paper on the subject before the Medical Society of Milwaukee County. The paper was long and rambling, garnished with occasional bursts of oratory of political-campaign type, but containing nothing regarding the nature of the remedy, its method of preparation, or the manner in which it is supposed to bring about the alleged wonderful results. It was devoted chiefly to criticism of the medical profession of the United States and to panegyric of Friedmann and those connected with him. After the paper was read, a number of well-known Milwaukee physicians discussed it freely and fully, and in a manner that left no doubt as to their marked disapproval and condemnation of the whole wretched Friedmann business. The society then passed resolutions, affirming its previous unfavorable opinions in every particular, with the unanimous vote of what was considered the largest attendance ever present at any of the society's meetings.

The Milwaukee newspapers, and for that matter, the newspapers of any city, might be expected to give a brief news-notice of the meeting of its local medical society. Most of the Milwaukee newspapers, with one exception, did this; the exception was the *Sentinel.* This paper reprinted Dr. Kellogg's address verbatim, leading off with display headlines: "MEDICAL MEN HEAR PRAISE OF FRIEDMANN—DEFENSE OF NEW TREATMENT BY DR. E. WELLS KELLOGG." This appeared in the most prominent position on the front page, and, in addition, occupied nearly the whole of one of the inner pages of the paper. While, however, the *Sentinel* devoted over a page of its space to Kellogg's defense of Friedmann, it gave just two inches, by actual measurement, to the action of the medical society in repudiating it, and did not report a single word of the discussion that followed the reading of the paper! We understand that the meeting at which the Kellogg paper was read lasted until midnight, and as the paper was reproduced verbatim in the next morning's issue of the *Sentinel,* it is fairly evident that the whole thing was in type before it was read.

The Milwaukee *Sentinel* is apparently a great deal more concerned in "boosting" the Friedmann "cure" than it is in giving the public both sides and letting it judge for itself. At least we may be justified in assuming that the *Sentinel's* wilful suppression of practically everything that was said against the Friedmann "cure" and its unheard-of "featuring" of a paper read before a scientific body are prompted by a lively sense of benefits to come — or already received. This much, at least, we may infer: If Friedmann's remedy were being introduced in a conservative, scientific, non-commercial way, the *Sentinel* would not have devoted a stickfull of space to it. The incident is typical of the disgraceful commercialism that is characterizing the exploitation of the Friedmann "cure" in the United States.

## Current Comment

### CONTAMINATION OF MILK BY TYPHOID CARRIERS

The importance of typhoid carriers in spreading typhoid fever is now so clearly recognized as to require no special emphasis. Sometimes it is difficult to find the carrier, and no doubt many instances of outbreaks due to carriers escape recognition on this account. An instructive instance showing how difficult it may be to find the carrier is described by Gruber.[1] It appears that in Munich typhoid fever has been steadily declining during recent years, except in a small part, in which the number of cases for a time persisted and even increased; women, especially servant-maids, being affected more often than men. In one house no less than nineteen cases occurred in the course of a few years. The milk, which was raw, was supplied from four different sources, and eventually it was found that three of the distributors obtained their milk at least in part from the fourth, so that in a sense it concerned only one dairy. The strains of bacilli isolated from the patients presented certain cultural peculiarities, and as the reward of much effort the same sort of bacillus was found in the suspected milk also. After a long time, and more or less by accident, a servant-maid working in the place from which the milk mostly came was discovered to be a fecal carrier, eliminating enormous numbers of bacilli, among which some gave cultural characters similar to those peculiar to the strains from the patients and from the milk. This person was removed from her work and isolated, whereupon the epidemic ceased. So far as could be determined, she had never had typhoid fever. The evidence indicates clearly that about one hundred and fifty cases of typhoid must be attributed to this carrier, who of course was quite innocent, not knowing anything of her condition and its results. This, then, is another instance showing the danger of raw milk and how easily it may become the vehicle of disease, even when the general conditions of milk production are quite satisfactory, which seems to have been the case here. Producers of so-called certified milk constantly face the danger of unwittingly employing a person who is a typhoid carrier. Gruber points out that, as things are, the best way is to pasteurize our milk properly.

## THE ALLEGED DECISION AGAINST THE AMERICAN MEDICAL ASSOCIATION

So long as the American Medical Association confined itself strictly to scientific work, only soft words, if any at all, were used in speaking of it. When, however, about eight years ago it began to fulfil its broader and more humanitarian functions—began to do things—then came a change. When it started to publish facts regarding fraudulent proprietary medicines; to lay before the public the damning truths regarding the Great American Fraud—"patent medicines"; to expose the commercialism that controlled too many of the medical schools—in a word, to attack various "vested interests" whose existence is largely due to the credulity of medical men and the public — the "soft words" were forgotten, and vicious, malignant opprobrium and epithet took their place. Recently, through newspapers, medical journals, circular letters, etc., the public and the medical profession have been led to believe that the courts have rendered a decision against the American Medical Association to the effect that the Association is illegally organized and is conducting its affairs contrary to law. It is not the policy, either of The Journal or of the Association to notice the many and varied attacks made on them—life is too short; but the Trustees, believing that many were being misled regarding the decision, have considered it wise to let the actual state of the case be known. Their statement of facts regarding this matter will be found on page 1920 of this issue.

## FULL-TIME, SALARIED CLINICAL PROFESSORS

For several years the necessity for having salaried full-time professors in charge of the laboratory branches in medical schools has been recognized, and in the recent agitation for improvements the number of such professors has been largely increased. It is only during the last few years, however, that serious consideration has been given to the matter of placing the clinical chairs on a similarly salaried basis. To a limited extent this has already been done in a few clinical chairs in the Yale Medical School, the University of Pennsylvania, Washington University, Leland Stanford Junior University, the University of California and others. In these institutions, however, the professor's practice has been limited to consultation practice, and there is no evidence that he is prevented from accepting fees for such service. In the provision accompanying the gift of $1,500,000, reported a few weeks ago as having been given by the General Education Board to the Johns Hopkins Medical School, the chairs of medicine, pediatrics and surgery are to be placed on a salary basis, and the holders of those chairs, although free to carry on what practice they desire, are not to charge fees for such work. They are to be given salaries, generous from the point of view of teachers and research men, but not large when compared with the enormous incomes received by the occupants of such chairs in some medical schools. The change is radical, but there are doubtless many clinical teachers who would gladly avail themselves of the fixed, though smaller income which will leave them free to make teaching and research in clinical medicine their first work in life. It may require time to bring about a proper readjustment of these matters and still retain for our medical schools the services of the best clinical teachers. Placing full-time, salaried professors in charge of the laboratory branches has developed a higher quality of teaching in those departments and added largely to the quantity and effectiveness of medical research. There is no doubt that the securing of full-time, salaried professors in the clinical chairs will have an equally beneficial effect; it will not only elevate the standards of clinical instruction, but also develop a more extensive research along the lines of clinical medicine, leading to a wider application of new discoveries in the treatment of disease. In the teaching hospitals connected with these medical schools, furthermore, the patients will secure treatment according to the latest and most improved methods developed through more careful study and research by these full-time professors. In any event the results of this innovation will be watched with interest and with confidence that no backward step has been taken.

## UNIQUE FERMENTATIVE CHANGES INDUCED BY BACTERIA

Recently we called attention[1] to the remarkable phenomena described by Neuberg and his collaborators in Berlin[2] involving vigorous fermentation, that is, liberation of carbon dioxid, when yeast is brought into contact with certain organic substances other than sugar. Pyrotartaric acid, for example, responds most vigorously by such a chemical decomposition when yeast-cells are transplanted into a solution of it. That this unusual manifestation is not the exclusive biochemical property of yeast-cells has now been demonstrated by investigations conducted in the university at Budapest by Drs. Karczag and Móczár.[3] They have selected as organisms typifying other low forms of life a series of bacterial forms. The results have been most striking in indicating that these organisms, in analogy with the yeast-cells, are likewise capable of inducing gas-production in the presence of pyrotartaric acid. It is particularly interesting to note that this organic compound is decomposed only by those bacteria which are accustomed to act on carbohydrates, and belong in general to the gas-producing group. For example, the colon bacillus, paratyphoid bacillus B and Gaertner's bacillus provoke gas-production in the presence of either glucose or pyrotartaric acid; the bacillus of dysentery and various types of streptococci and staphylococci fail to call forth gas-production in either. The investigation of the gas resulting from the unique reaction described above shows that it is not primarily carbon dioxid, which is the case when yeast is the active agent involved. Over 90 per cent. of the gases formed may be hydrogen with a small residue of carbon dioxid. Corresponding with this difference between the fermentative phenomena of bacteria and those of yeast toward pyrotartaric acid, the other products of this fermentation are unlike in the two cases. Where yeast is concerned, acetaldehyd arises. In the case of the bacteria referred to, however, propionic and butyric acids among other volatile products have already been identified. These observations are among the beginnings of the studies which promise to place the chemistry of the fermentative reactions on a firmer basis of definite knowledge. They further indicate that the type of carbohydrate fermentation with which chemistry has so long been familiar is but one manifestation of the biochemical activity of the numerous lower forms of organic life which play prominent parts in all sorts of physiologic and technical performances.

## THE SUSCEPTIBILITY OF ANIMALS TO HUMAN STRAINS OF TRYPANOSOMES

In connection with the investigations of the Scientific Commission of the Royal Society of London which is engaged, under the leadership of Surgeon-General Sir David Bruce, in a study of the trypanosomes causing disease in man in Nyasaland, attention has been directed to the effect of the human strains on various animals. This aspect of the subject is obviously not without importance; for the interrelation of man and animals is such in respect to the possibility of disease transmission that they can no longer be considered as entirely independent of each other where infection furnishes problems to contend with. One or the other may become the unsuspected host of species of invading organisms relatively harmless to itself, but of serious import to its neighbor. From the latest report[1] it appears that the trypanosome causing disease in man in Nyasaland is fatal to goats, sheep, dogs and the smaller laboratory animals, killing them, without exception, in a few weeks. It is less virulent to cattle, many of which escape. No difference in virulence was made out in five strains from man which were tested and which probably belonged to the species *Trypanosoma brucei*.

## HOW FAR CAN FLIES TRAVEL?

The growing evidence that insects of various types may become carriers of disease has aroused an unusual interest in the habits and "natural history" of those species, like the mosquitoes and flies, which are the foremost recognized offenders. Their modes of breeding and their normal habitats have been assiduously investigated, as have been the migratory possibilities for the individual types under consideration. The life history of the mosquito is familiar to every reader of a Sunday newspaper or popular magazine. The knowledge of where and how it breeds, whence it comes, whither it travels and how it enters into familiar and unhygienic relations with man, is disseminated everywhere. In most of the stories involving the travels of the mosquito, the species responsible for the infections in which it plays a demonstrated part is made to remain comparatively near to its original breeding-place. At best these insects fly a few hundred feet or are perchance wafted a mile or so on rare occasions in a gust of wind. Statements concerning the restricted travel of the house-fly and the stable-fly have been much of the same order. It is maintained, for example, that house-flies seldom stray more than five hundred yards from their breeding-places, although some English observations prove that they may go a mile from an infected dump to the nearest village. A curious incident in connection with the Cleveland antifly campaign has brought some rather unexpected, yet positive evidence on the the migration possibilities of flies. A request was sent for some means of relief from the plague of flies on the cribs of the water-works, situated a mile and a quarter, five miles and six miles out in Lake Erie north of the city. An investigation was undertaken by C. F. Hodge,[1] whose vigorous activities in the antifly crusade in the United States are widely appreciated. The invasion of the flies could not be charged to passing steamers or to conditions obtaining on the cribs. Although tenders live on the cribs, there are no animals and there is absolutely nothing in which flies of any kind could breed. All garbage and waste matters are dumped immediately into the lake or are put into a tight incinerator and burned daily. Lake steamers pass within about half a mile of the cribs, but none of the men had ever noticed any evidence of flies coming from them. All the crib-tenders maintain that a south wind brings a cloud of flies from the city and that a north wind carries them away. No smaller boats were anywhere near the cribs that day and seldom come near them. The only explanation which occurs to Hodge seems to be that the flies are blown at least six miles off shore, and that they gather on the cribs as temporary resting places. Attraction of any other sort cannot be a strong factor, else they would remain on shore, attracted by the animals and men along the docks and the much richer food-supply. He says that while not entirely conclusive, the evidence seems strongly to support the theory that flies of certain kinds are able to travel much farther than is commonly supposed. Flies which have traveled these long distances appear to be ravenously hungry and some of them bite viciously. It is not difficult to trap them under these conditions.

### THE COLD BATH IN FEVER

Stewart[1] advances the opinion that the rise of temperature in fever is incidental to a general contraction of the peripheral vessels by which more blood is supplied to the internal organs, particularly to the vessels of the splanchnic circulation. He suggests that the contraction of the peripheral vessels is a therapeutic process to be favored rather than opposed, and therefore that the means taken to reduce temperature should be such as will abstract heat and still maintain the contraction of the vessels of the extremities. For this purpose he regards the cold bath as especially suitable because it abstracts heat without dilating the cutaneous vessels. The theory on which cold bathing in fever has generally been practiced is that it acts as a tonic to the nervous system and by the production of a reaction affects better distribution of the blood. It has been advised to rub the patient while in the bath and after his removal so as to secure a reaction indicated by redness and warmth of the extremities; but if the opinion of Stewart is true, and if his experiments are confirmed, we shall be compelled to change our views as to the importance of securing a reaction. If it is desirable to maintain the internal congestion, the cold bath is an admirable means to effect this purpose, but we should avoid the reaction or at least take no pains to produce it by rubbing. The rubbing, by attracting the blood from the internal organs to the periphery, would seem calculated to defeat the purpose of the contraction of the peripheral vessels which characterizes the fever.

### PARENTERAL VERSUS ORAL NUTRITION

Scarcely ten years have elapsed since Oppenheimer[2] proposed the word "parenteral" to express a mode of introducing foodstuffs into the body by some path other than *per os*. Parenteral nutrition has thus become contrasted with oral feeding, and the new term has already found a wide acceptance. The possibilities and problems of furnishing food to the organism, subcutaneously, intravenously, intraperitoneally, or even intramuscularly, have been the subject of discussion, particularly with reference to conditions of a pathologic nature when the usual practice of feeding by way of the mouth has to be abandoned for some reason or other. The result of most of the work in this field has been to demonstrate the futility of attempting to furnish food to the cells of the body in any form other than that in which it is usually prepared by the digestive processes. Paradoxical as it may sound, most of the ordinary nutrients behave like poisons in the body when they are introduced as such parenterally and meet the tissue of the individual in their native form. Few carbohydrates can be injected directly, that is, parenterally, and become utilized in any direct manner. Cane-sugar, for example—one of the commonest of dietary ingredients—is managed like a foreign substance whenever it reaches the blood-stream in its original chemical form. The kidneys quickly eliminate it in good measure. Appropriately emulsified fats may experience a somewhat better fate, though they tend to remain deposited a long time at the site of their parenteral introduction, unless it be directly into the swiftly moving blood-stream. For proteins the practical possibilities of parenteral administration have been eliminated almost entirely. With the danger of death by anaphylactic shock ever present, few physicians would venture to furnish unaltered proteins to patients by a parenteral route. The hope of the future in the direction of parenteral nutrition lies in devising satisfactory practical schemes for employing not the dangerous native proteins, fats and carbohydrates, but rather such digested representatives thereof as are normally prepared out of our foodstuffs in the alimentary processes and are furnished for absorption. As we have remarked on previous occasions, there is an excellent opportunity for useful work in this direction to supplant oral nutrition whenever for the time being it becomes a practical impossibility.

## *Medical News*

### GEORGIA

**Epidemic Diseases.**—It is reported that 10 per cent. of the people of Savannah are suffering from dengue.

**Honor to Memory of Georgia Physician.**—At the State Normal School, Athens, November 1, was celebrated the anniversary of the birth of Dr. Crawford W. Long, discoverer of ether-anaesthesia.

**New Medical Board Officers.**—At the first meeting of the new State Board of Medical Examiners, the following officers were elected: president, Dr. Jarrett W. Palmer, Ailey; vice-president, Dr. G. Fleming, Waycross; secretary, Dr. Charles T. Nolan, Marietta.

**Tuberculosis Institute Incorporated.**—A petition has been filed for the incorporation of the W. G. Raoul Foundation. Captain Raoul set aside a bequest of $100.000, directing that it be used to combat tuberculosis by educating the people and by working for prevention as well as by treating those ill with the disease.

**Personal.**—Dr. Edgar L. Hawley, Atlanta, was shot but not seriously wounded by a burglar, November 1.——Dr. Charles F. Curtis, Decatur, was awarded a verdict of $750 October 29 in a suit for $10,000 against the city of Atlanta for injuries alleged to have been received through the city's carelessness in leaving a dangerous hole in one of the streets.——Dr. and Mrs. Dunbar Roy, Atlanta, have returned from Europe.

**New Officers.**—Tenth District Medical Society at Augusta, November 5: president, Dr. George A. Traylor; secretary-treasurer, Dr. H. William Shaw, both of Augusta.——Georgia Surgeons' Club, organized at Atlanta November 5: president, Dr. Edward C. Davis, Atlanta; vice-president, Dr. Thomas J. McArthur, Cordele; secretary-treasurer, Dr. Robert M. Hardin, Rome. The club decided to visit New Orleans as a body in February, and to take other medical trips later on from time to time during the year.

## ILLINOIS

**Children's Clinic.**—St. Joseph's Hospital, Alton, has established a children's clinic which is open every Tuesday and Friday morning, from 8 to 11 o'clock.

**Personal.**—Dr. and Mrs. William H. Mercer, Raymond, have sailed for Europe.——Dr. George R. Smith, Bloomington, who was stricken with cerebral hemorrhage recently, is reported to be improving.

**New Officers.**—Southern Illinois Medical Association, thirty-eighth annual session at Duquoin November 7: president, Dr. Charles W. Lillie, East St. Louis; secretary, Dr. Alonzo B. Capel, Shawneetown. Mount Vernon was selected as the next place of meeting.

**State Hospital Site Selected.**—The members of the State Board of Administration, on November 15, definitely settled that the new million-dollar hospital for the insane should be located on the northeastern portion of the Kilpatrick farm, 1½ miles west of Upper Alton.

### Chicago

**Red Cross Branch to Be Established.**—Mr. Ernest P. Bicknell, director of the American Red Cross, announced that the work of the national body has become so heavy that it has been decided to divide the work into four divisions, of one of which Chicago is to be the headquarters.

**Asked Increased Appropriation.** — Health Commissioner Young has asked an appropriation of $1,190,278 for the Department of Health for the coming year. The actual increase over the last appropriation is $450,000, of which $335,000 is for reorganization of the department and increase in the staff.

**Ophthalmologic Banquet.**—The meeting of the Chicago Ophthalmological Society, November 17, was preceded by a reception and banquet in honor of Lieut. Col. Robert H. Elliot, I.M.S., Madras, India; Dr. Edward Jackson, Denver; Dr. George Edmund de Schweinitz, Philadelphia, and Dr. John E. Weeks, New York City.

## KANSAS

**Personal.**—Dr. George Nealley, Lansing, is reported to be seriously ill as the result of a cerebral hemorrhage.——Dr. Andrew Pearson, Wakefield, was seriously injured in an automobile accident October 25.——Dr. Mark L. Bishoff, Topeka, has been appointed superintending physician of the Santa Fe Employees' Hospital, Fort Madison, Ia.

**Society Defends Fryer.**—At the meeting of the Leavenworth County Medical Society September 18, resolutions were unanimously adopted which enter a vigorous protest against and condemn the action of the board of managers of the Western Branch National Home for Disabled Volunteer Soldiers, in making charges against Dr. John L. Fryer, surgeon of the Western Branch, and requesting his resignation; bearing testimony to the esteem in which Major Fryer is held by the members of the society, and to his efficiency in the management of the Soldiers' Home Hospital.

## KENTUCKY

**New County Sanatoriums.**—At the election November 4, Fayette, Herderson and Christian counties voted to establish tuberculosis sanatorium districts.

**Personal.**—Dr. John H. Buschemeyer has been elected mayor of Louisville.——Dr. John H. Van Deren, Cynthiana, was painfully injured by the overturning of his automobile between Cynthiana and Paris, November 5.——Dr. William R. Ruble, Smith's Grove, is reported to be seriously ill in a sanitarium in Cincinnati.——Dr. C. W. Froedge, Glasgow, fell from his horse October 20, fracturing his right forearm.——Dr. John W. Watson, Henderson, was seriously injured in a runaway accident recently.

## LOUISIANA

**New Officers.**—Ascension Parish Medical Society organized at Donaldsonville: president, Dr. E. Kittredge Simms, Donaldsonville; secretary-treasurer, Dr. Allen W. Martin, Alexandria.

**Personal.**—Dr. and Mrs. William T. O'Reilly, New Orleans, celebrated their silver wedding anniversary October 24.——Dr. and Mrs. Otto Lerch, Dr. and Mrs. L. Sexton and Dr. Edmund Moss, all of New Orleans, have returned from abroad.

**Clinic for Italians.**—A free clinic for the Italian poor of New Orleans was opened November 10 by the Italian Hall Association. The clinic is open from 8:30 to 9 in the morning and the physicians of the staff alternate in duty at the clinic.

**New Régime at Charity Hospital.**—Dr. C. B. Wilkins assumed charge as superintendent of Charity Hospital, New Orleans, October 1. Dr. Wilkins is receiving the most cordial support both from the management of the hospital and the visiting and resident staff. The services have been divided as follows: Surgical division, nine chiefs—Drs. Rudolph Matas, Frederick W. Parham, Hermann B. Gessner, John Smyth, Martin, Felixi A. Larue, Joseph A. Danna, Stephen W. Stafford and James M. Batchelor; medical division, six chiefs—Drs. John B. Elliott, Jr., John T. Halsey, George S. Bel, Wellman, George F. Patton and Joseph M. Elliott; gynecological and obstetrical division, four chiefs—Drs. Paul Michinard, C. J. Miller, Clark and William Kohlmann; division of children's diseases, medical, three chiefs—Drs. William W. Butterworth, Laurence R. DeBuys and Charles A. Borey; orthopedics and surgical diseases, children's division, three chiefs—Drs. Erasmus D. Fenner, Herman Oechsner and Edward S. Hatch; ear, nose and throat division, three chiefs—Drs. Charles J. Landfried, Otto Joachim and Homer J. Dupuy; eye division, two chiefs—Drs. Marcus Feingold and Theodore J. Dimitry; skin division, three chiefs—Drs. Isadore Dyer, Henry E. Menage and Joseph N. Roussel, and genito-urinary division, three chiefs—Drs. Charles L. Chassaignac, Joseph Hume and Abe Nelken. Each visiting chief has been assigned the wards, beds and out-door clinics for which he is to be responsible. The remainder of the visiting staff has been graded and assigned to service under the different chiefs. The following resident medical officers have been appointed: Dr. Lewis B. Crawford and Dr. Lucien A. Fortier to be resident surgeons; Dr. William B. Chamberlain to be resident gynecologist and obstetrician; Dr. Houston Staring to be resident physician.

## MAINE

**Personal.**—Dr. Arthur G. Wiley, Bar Mills, is said to be seriously ill with typhoid fever at his home.——Dr. Willis G. Jefferson, Portland, severed his right hand at the wrist November 4. It is supposed the act was done in a fit of religious frenzy.

**Fairfield Sanatorium.**—The Central Maine Association for the Relief and Control of Tuberculosis is erecting at Fairfield a new building for incipient cases with a capacity of forty beds, to replace the building destroyed by fire in July. It also plans to erect a hospital for advanced cases, a cottage for children suffering from tuberculosis and an administration building. The medical staff has been reorganized with Dr. Auguste U. Des Jardins, Waterville, as medical director, and the following consulting board: Drs. Addison S. Thayer, Portland, William C. Peters, Bangor, O. C. S. Davies, Augusta, and Frederick C. Thayer, Waterville, consulting physicians; Dr. Donald B. Cragin, Waterville, consulting surgeon, and Dr. John F. Hill, Waterville, consulting laryngologist.

## MASSACHUSETTS

**Quincy Wants Contagious Hospital.**—An order appropriating $35,000 for the new hospital for contagious diseases in Quincy has been introduced into the City Council.

**Personal.**—Dr. Frank G. Fay, Worcester, is chief legatee in the will of Louisa C. Whittemore of Worcester, who died a few days ago.——Dr. John H. Gifford, Fall River, has been appointed society medical examiner of Bristol County.

**Medical Alumni Meet.**—The Harvard Medical Alumni Association held a reception November 14 at the Harvard Medical School and the neighboring hospitals. At the medical school all the laboratories were open and demonstrations were given by members of the staff, and special clinics and demonstrations were also offered at the hospitals near the medical school. An informal reception was held in the Administration Building, after which light refreshments were served.

**The School for Health Officers.**—As set forth in the Monthly Bulletin of the Massachusetts State Board of Health, September, 1913, the Massachusetts Institute of Technology and the Harvard University have joined hands in establishing a school for health officers. The department of preventive medicine of Harvard and the department of sanitary engineering of the Graduate School of Applied Science of the same institution and the department of biology of the Massachusetts Institute of Technology are the departments having supervision over the school. The school for health officers will be an administrative entity under the charge of an administrative board, at present to be composed of Prof. W. T. Sedgwick of the Institute of Technology; Prof. M. J. Rosenau of the Harvard Medical School and Prof. Geo. C. Whipple of the Graduate School of Applied Science. Professor Rosenau will be director of the school. Graduates in medicine of Harvard University and other recognized medical schools will be admitted on their records, and registered as candidates for the certificate of public health. Bachelors of science in biology and public health of the Institute of Technology and other recognized institutions may also be admitted. Persons having certain other degrees and experience from other schools and colleges may also be admitted to the course with certain conditions. Special students not candidates for the certificate of public health who desire to fit themselves for some special field will be admitted and may take any course for which they are properly qualified. While the medical degree is not required for the certificate of public health, candidates are advised to obtain this degree first, as it is felt that the higher positions in public health work come more readily to those who have a medical degree. There will be no prescribed curriculum for the certificate, but they will be required to elect a schedule of courses to meet their needs. The school for health officers will not interfere in any way with the present doctor of public health degree (Dr. P.H.) now offered by Harvard University.

### MICHIGAN

**New Quarters for Medical Society.**—Dr. Edward G. Martin, Detroit, announced at the last meeting of the Wayne County Medical Society that the new auditorium, which will accommodate 500 persons, will be completed in January next.

**Personal.**—Dr. Daniel H. Eaton, Kalamazoo, suffered a fracture of the skull in an automobile accident, November 5.——Dr. Robert L. Dixon, Lansing, secretary of the State Board of Health, has resigned to accept the superintendency of the State Epileptic Farm Colony at Wahjameja.——The Lansing Clinical Club gave a complimentary dinner to Dr. Louis W. Toles, president of the club, November 4.——Dr. Hugh Cary, Detroit, is reported to be critically ill.——Drs. Thomas A. Baird, Edward C. Warren, J. William Gustin, George W. Moore, Munger, and Virgil L. Tupper, Bay City, have returned from Europe.——Dr. Joseph A. M. Clark, Cascade, was painfully injured in a collision between his motor car and a street car in Grand Rapids, October 27.

**New Officers.**—Michigan Association for the Prevention and Relief of Tuberculosis at Kalamazoo November 7: president, Dr. Herman Ostrander, Kalamazoo; secretary, Miss Carol S. Walton, Ann Arbor; treasurer, Dr. Henry J. Hartz, Detroit.——Tri-County Medical Society at Cadillac, November 6: president, Dr. Otto L. Ricker, Cadillac; vice-president, Dr. Albert E. Stickley, Mesick; secretary-treasurer, Dr. Rudolph J. E. Oden, Cadillac.——Eaton County Medical Society at Charlotte, November 6: president, Dr. C. A. Stinchcombe, Eaton Rapids; secretary-treasurer, Dr. Cassius S. Sackett, Charlotte.——Southwestern Michigan Eye, Ear, Nose and Throat Society organized at Kalamazoo, November 4: temporary chairman, Dr. Edward J. Bernstein, Kalamazoo; temporary secretary, Dr. Wilfrid H. Haughey, Battle Creek.——Genesee County Medical Society at Flint, October 28: president, Dr. Mark S. Knapp; secretary, Dr. Robert D. Scott, both of Flint.——Tuscola County Medical Association at Caro: president, Dr. Robert H. Steinbach, Richville; secretary-treasurer, Dr. Wynne C. Garvin, Millington.

### MINNESOTA

**New Officers.**—Blue Earth Valley Medical Society at Blue Earth October 30: president, Dr. Peter F. Holm, Wells; secretary, Dr. John A. Broberg, Blue Earth (reelected).

**State to Sell Antitoxin at Cost.**—Dr. Henry M. Bracken, Minneapolis, secretary of the State Board of Health, has notified local boards throughout the state that the department of health is now prepared to supply diphtheria antitoxin at cost.

**Southern Minnesota Physicians to Meet.**—At the annual meeting of the Southern Minnesota Medical Association to be held in Mankato, December 2 and 3, arrangements have been made for addresses by Dr. James B. Herrick, Chicago, on "The Bundle of His," with lantern slide demonstrations, by Dr. Ludvig Hektoen, Chicago, on "The Cause of the Crisis in Pneumonia," and by Dr. Robert H. Babcock, Chicago, on "Acute and Sub-Acute Endocarditis," with specimens. Dr. Babcock will also hold a clinic on diseases of the heart and lungs. These papers from outside men are in addition to a number of excellent articles by members of the profession of Southern Minnesota.

### NEBRASKA

**For Nebraska Newspaper Readers.**—The owner of the Omaha *World-Herald* is Senator Gilbert M. Hitchcock, and in one issue of his newspaper one reads a half-page advertisement, headed "Cancers Cured Without the Dreaded Plaster Treatment"—a full half-page of delusion for the victims of an incurable disease. While the proprietor is kept busy at Washington his journal fairly reeks with an odious class of medical advertising. But who is downhearted? Ten years ago United States senators were giving out patent-medicine indorsements to the Great American Fraud, testimonials which they were willing to see published broadcast in newspaper advertisements. Ten years hence newspapers owned by United States senators will be turning down quack advertisements, if not because senators have improved by that time, then because their reformed competitors will have forced them into virtue's way. All Senator Hitchcock needs is a little time to think it over.—*Collier's Weekly.*

### NEW YORK

**An American Spa.**—Dr. Paul Haertl, head of the Royal Chemical and Balneologic Laboratory, Bad Kissingen, Germany, arrived in New York November 12. He came to this country on the solicitation of Dr. Simon Baruch, New York City, who had urged the reservation commission, of which George Foster Peabody is chairman, to obtain counsel and cooperation of Dr. Heartl in the final plans for making Saratoga Springs a health resort on which physicians and the public may depend. The state has expended $1,000,000 in the purchase of the mineral water rights and 250 acres of land with the idea of developing a great health resort.

#### New York City

**Personal.**—Mr. Frederick B. Morlock, for ten years chief clerk and assistant treasurer of the Presbyterian Hospital, has been appointed superintendent of the Flower Hospital.——Dr. Joseph W. Moore of Manhattan State Hospital, Wards Island, has recently been appointed first assistant physician at the Matteawan State Hospital.——Dr. D. Bryson Delavan has recovered from a serious operation which he underwent last spring and has resumed his practice.

**All Milk for Drinking Purposes Must Be Pasteurized.**—Health Commissioner Lederle has announced that the Board of Health has adopted two regulations affecting the sale of raw milk. The first amends the sanitary code so as to forbid the sale of raw milk for consumption on the premises and removes Grade B, the class of raw milk that was formerly permitted to be sold under that designation. Only milk produced under regulations governing the sale of certified milk can be sold raw; all other grades of milk must be pasteurized. This action is the last step in a carefully worked out plan that has gradually been put into effect during the past four years to bring about the pasteurization of the entire milk supply of the general market of New York City. Warnings have also been issued to housewives by the health department warning them that they are liable to prosecution for returning to the drivers of milk wagons bottles which have not been properly cleansed.

**Large Donation to Medical School.**—The Board of Trustees of Cornell University announces that a gift of about $4,000,000 has been made to endow the Cornell University Medical College. It is understood that the donor is Col. Oliver Hazard Paine, New York City, who gave $500,000 several years ago for the establishment of the school. This endowment fund will provide an annual income of $200,000 for the medical school. This is one of the greatest individual gifts ever given to an educational institution, and it is especially pleasing that it is given for the advancement of medical education. With this increased endowment Cornell is given an exceptional opportunity to develop a thorough, systematic and complete course of training for medical students, under the ablest teachers and in an atmosphere of medical research. The school cannot fail to turn out better-equipped doctors, imbued with a faith in greater things to come in medicine, and enthusiastic in their desire to aid in solving the complex problems of alleviating and preventing disease.

**Babies' Welfare Work Reduces Infant Mortality.**—The Babies' Welfare Association has announced the results of an investigation made by the Department of Health, covering the period of hot weather. Out of 33,000 babies under 2 years of age enrolled in the fifty-five milk stations of the department. between January 1 and November 1, the death rate was only four to a thousand, in spite of the fact that a large number of these babies were suffering from digestive disturbances at the time of enrolment. During June, July and August only 113 milk station babies died. At the same time the death-rate of the babies of the city under 2 years of age was 75 per thousand. There have been 493 fewer deaths of infants under 1 year of age in all the boroughs than during the same period of time in the previous year. If this record continues for the remainder of the year New York will be able to show an infant mortality of only 100 or less for each one thousand births.

**New Hospitals.**—The facilities for the treatment of tuberculosis in New York City were enlarged by the opening of a new hospital known as Sea View, located at Castleton Corners, Staten Island, at a cost of more than $3,000,000. Eighty patients have already been admitted to the institution which has accommodation for 1,000 patients who are housed in eight pavilions arranged in a semi-circle so that sunlight may enter every room and ward.——The new building of the Herman Knapp Memorial Eye Hospital at Fifty-Seventh Street and Tenth Avenue has been opened. The hospital was founded by the late Herman Knapp in 1869 and has been known as the New York Ophthalmic and Aural Institute. In this institute more than 420,000 patients have received treatment. The new building is a seven-story, fire-proof structure with the most modern equipment for the treatment and study of diseases of the eye.——The corner-stone of the new Hospital for Deformities and Joint Diseases was laid November 5. The principal address was delivered by Dr. Abraham Jacobi.

## NORTH CAROLINA

**Sanatorium to Open.**—The State Sanatorium for Tuberculosis, Montrose, is to be opened December 1. The institution has accommodation for more than 100 patients and many applications have already been received.

**Personal.**—Dr. James W. Magee, Raleigh, who has been ill in his home for several weeks, has recovered and has resumed practice.——Dr. John L. Carroll, Asheville, his wife, sister and brother sustained painful injuries in an automobile accident recently, but all are reported to be recovering.

**Fire in Medical School.**—A fire in the Leonard medical building, November 6, burned out the laboratories on the two upper floors and seriously damaged the laboratory on the first floor. The walls of the building are intact but the roof was badly damaged. The building is being repaired and will be reequipped as soon as possible.

**Exhibits at Teachers' Assembly.**—During the annual session of the North Carolina Teachers' Assembly in Raleigh, November 26-29, Dr. Albert Anderson, superintendent of the State Hospital for the Insane, will have a mental hygiene exhibit and will hold conference for the benefit of the teachers. The State Board of Health will also have an exhibit.

**Antityphoid Vaccination.**—The State Board of Health announces: "Vaccination against typhoid has successfully passed all the tests of science and practice, and has won as prominent a place among sanatoriums as has vaccination against small-pox." The board, having established a plant for the preparation of antityphoid vaccine under authority granted at the last session of the state legislature, invites physicians who wish to employ the vaccine to apply for it as it will be furnished without cost.

**School for the Feeble-Minded.**—At the recent session of the legislature an appropriation of $70,000 was made to complete the buildings and open the State School for the Feeble-Minded, Kinston, on which work was begun about two years ago. Originally the state appropriated $60,000, later adding $10,000, which was supplemented by donations from citizens of Kinston and Lenoir, making the actual value of the state's investment in the institution fully $120,000. The work of Dr. Alfred A. Kent, Lenoir, state senator, and Dr. James A. Gordon, Jamestown, state representative, was indefatigable and their efforts were ably aided by Dr. Ira M. Hardy, later secretary of the board of trustees and superintendent of the institution. Dr. Hardy has given his entire time to this work for the last two years, and expects the building will be completed and the school opened next year.

## PENNSYLVANIA

**New Officers.**—Bucks County Medical Society at Doylestown, November 14: Dr William LeComte of Bristol, president.

**Hospital at Mine.**—The Reading Coal and Iron Company has established, for the benefit of its employees, a hospital at its Locust Spring colliery.

**Personal.**—Dr. Frederick W. Brown has been elected mayor of Franklin.——Dr. Howard Pursell has been appointed president of the Bristol Board of Health.

**Hospital Staff Entertained.**—The physicians of the staff of the Wilkinsburg State Hospital were given a dinner November 6, by Dr. William C. Reese, Scranton.

**Beriberi on Ship.**—A case of beriberi was discovered among the Chinese crew of the British steamship *Strathmore.* The victim is in the Quarantine Hospital at Marcus Hook.

**Contract Awarded.**—A contract has been awarded for the brick and stone buildings to be erected at Fairview, Pa., for the State Hospital for the Criminal Insane. The buildings will cost $135,000.

### Philadelphia

**Hospital to Change Location.**—The Lebanon Hospital, now located at Fourth and Spring Garden Streets, has purchased three large properties at Seventh and Columbia Avenue and plans to erect a new hospital on this site at a cost of $40,000. This institution was established in 1909 and its work has expanded to such an extent that the present building is wholly inadequate to the demands of this congested section of the city.

**To Standardize Training of Nurses.**—At the eleventh annual session of the Graduate Nurses' Association of Pennsylvania, held November 14 in the College of Physicians, plans for the standardization of the training of nurses were considered. The nurses discussed the advisability of combining small nurses' training schools with large ones in order to increase the efficiency. The committee of fifteen nurses was appointed to cooperate with the State Board of Examiners in working for a standard system of education in all nurses' training schools throughout the state.

**Personal.**—Dr. Robert Tait McKenzie, professor of physical education in the University of Pennsylvania and a sculptor of renown, has completed a medallion of Dr. Horatio R. Storer of Newport, R. I.——Mr. Daniel Baugh, on behalf of the Jefferson Medical College, has sent out invitations for a reception at his residence, December 2. The guests of honor will be Dr. W. W. Keen, emeritus professor of surgery; Dr. W. Joseph Hearn, emeritus professor of clinical surgery; Dr. James C. Wilson, emeritus professor of medicine; Dr. James W. Holland, emeritus professor of chemistry and toxicology.——Dr. Herbert M. Goddard has been appointed to the post of laryngologist to the Jewish Hospital.——Dr. Charles H. Frazier, professor of clinical surgery at the University of Pennsylvania, was elected president of the Public Charity Association of Pennsylvania, October 30.

**County Society Condemns Critics of Judiciary.**—At a recent meeting of the Philadelphia County Medical Society a resolution was adopted repudiating the attack made upon the judiciary of the courts of common pleas in a paper read at the recent meeting of the state society in this city. The resolution was, in part, as follows: That the board of directors of the Philadelphia County Medical Society deplore the criticism of the judiciary of the Common Pleas Courts of Pennsylvania, recently made by a member of the Medical Society of the State of Pennsylvania during the recent session of the society in Philadelphia. The board of directors feels that the members of the profession in Philadelphia who appear from time to time before our courts of common pleas have been treated with the utmost consideration, courtesy and justice by those presiding. Judge Norris S. Barrett, of the Court of Common Pleas has, in a communication, thanked the local county society for this action.

**Officers Elected.**—At the business meeting of the Philadelphia County Medical Society, October 15, the following nominations were made for officers to serve during the year 1914: president, Dr. William D. Robinson; vice-president, Dr. Herbert A. Hare; secretary, Dr. William S. Wray; treasurer, Dr. Edward A. Shumway; directors, Drs. Herman B. Allyn, G. Morton Illman, John D. McLean. The following delegates were named for the State Medical Society: Drs. Wilmer Cruson, G. A. Knowes, Thomas R. Currie, J. F. Schamberg, and William M. Welsh. The following officers were nominated at the regular quarterly meeting of the Medical Club, October 17: president, Francis X. Dercum, Samuel D. Risley, Wilmer Krusen; first vice-president, McCluney Radcliffe; secretary, William S. Wray; treasurer, Lewis H. Adler; governor, Clarence P. Franklin; directors, Ellwood R. Kirby, William E. Hughes, Swithin Chandler, Paul Judd Sartain, Alexander McAllister, E. Horgan, Matthew Woods, H. H. Whitcomb, Herbert B. Carpenter, Rae S. Dorsett.

## SOUTH CAROLINA

**State Society Wins Suit.**—*In the case of the South Carolina Medical Association against Frank B. Griffith*, a suit which grew out of the building of the Roper Hospital, Charleston, the opinion of the United States District Judge, filed October 4, is in favor of the society.

**Personal.**—Dr. Ernest M. Rast has been reelected intendant of Cameron.——Dr. Pinckney V. Mikell has succeeded Dr. Samuel E. Harmon as a member of the Health Board of Columbia.——Dr. James L. Bolt, Easley, has been elected a member of the house of representatives from Pickens County.

**New Officers.**—Charles County Medical Association at Charleston November 6: president, Dr. William H. Johnson, Charleston; secretary, Dr. Michael M. Edwards.—Third District Medical Association at Abbeville: president, Dr. Thomas L. W. Bailey, Clinton; secretary-treasurer, Dr. J. E. Presley, Abbeville.

## WISCONSIN

**Sanatorium Notes.**—The Eau Claire County Tuberculosis Sanatorium, recently erected at a cost of $36,000, is ready to receive patients.——The board of control has decided to establish a tuberculosis camp at Tomahawk Lake, at an expense of about $10,000.

**Inebriate Ward Ready.**—The inebriate ward of the Milwaukee County Hospital for the Insane has been opened, and instead of sentencing habitual drunkards to the House of Correction for short periods, they will now be committed to the inebriate ward for treatment.

**Antituberculosis Officers Elected.**—At the fifth annual meeting of the Wisconsin Antituberculosis Association held in Milwaukee, the following physicians were elected officers: president, Dr. Mazyck P. Ravenel, Madison; second vice-president, Dr. Gustave Windesheim, Kenosha; recording secretary, Dr. Clarence A. Baer, Milwaukee, and executive secretary, Dr. Hoyt E. Dearholt, Milwaukee.

**Hospital Notes.**—A five-story, fire-proof building will be erected by the Mount Sinai Hospital Corporation in Milwaukee at Twelfth and Cedar streets. The building will be of brick and stone construction and will cost about $160,000.——The Common Council of Waukesha has selected a site for a municipal hospital at North Street and Delafield Avenue.——An addition to the Evangelical Hospital, Milwaukee, was authorized by the Board of Directors at its last meeting. The annex will adjoin the present structure and will cost $30,000.

**Personal.**—Dr. Horace M. Brown, Milwaukee, has returned from abroad.——Drs. A. L. Cludas and Louis Clonchlin of Mexico City were recent visitors in Milwaukee.——Dr. Fred Johnson, North Freedom, has been appointed district officer of the State Board of Health with headquarters at Eau Claire.——Dr. George N. Hidershide, Arcadia, a Civil War veteran, has received a medal of honor from the war department.——Dr. Mazyck P. Ravenel, Madison, has been appointed chairman of the national committee on standard methods for the bacteriological examination of milk.——Dr. Charles O. Latham, Darlington, has been appointed resident physician at the State Reformatory for Boys, Green Bay.——Dr. Helen A. Binnie, Milwaukee, has been appointed medical superintendent of the Miners' Hospital, Frostburg, Md.

## GENERAL

**Congress Elects Officers.**—The following officers of the Clinical Congress of Surgeons of North America were elected, Thursday, November 13, 1913; president, Dr. John B. Murphy, Chicago; vice-president, Dr. George E. Armstrong, Montreal, Quebec; secretary, Dr. Franklin H. Martin, Chicago (reelected); treasurer, Dr. Allen B. Kanavel, Chicago (reelected); business manager, Mr. A. D. Ballou, Chicago (reelected). The next meeting of the congress will be held in London, England, the fourth week in July, 1914. A special committee was appointed to take up the work of standardization of surgery. This committee is composed of Drs. Lewis S. McMurtry, Louisville, Ky.; Charles H. Peck, New York City; Henry P. Newman, San Diego, Cal.; William L. Cousins, Portland, Me., and Charles A. Davison, Chicago.

**American College of Surgeons.**—The convocation exercises of the American College of Surgeons were held in Chicago, November 12. The names of the surgeons who were made members of the college were read by the secretary, Dr. Franklin H. Martin, Chicago, and the president, Dr. John M. T. Finney, Baltimore, pronounced them fellows of the college. The number admitted to the organization was 1,050.

**North Pacific Surgical Association.**—The surgeons of Oregon, Washington and British Columbia met in Portland, Ore., March 9, 1912, and organized the North Pacific Surgical Association, with a charter membership limited to thirty-six, and adopted the following qualifications for membership: "Candidates for membership shall be 30 years of age, graduates of at least five years' standing of recognized schools of medicine, members in good standing of their state and provincial medical associations, whose achievements in surgery, as practitioners, operators, investigators, teachers or authors, entitle them to membership." The following officers were elected for the year 1913: president, Dr. C. W. Sharples, Seattle; vice-presidents, Drs. A. S. Monro, Vancouver, B. C., and Andrew C. Smith, Portland; secretary-treasurer, Dr. J. B. Eagleson, Seattle; councilor, Dr. A. Raymond, Seattle, and recorder, Dr. J. M. Neff, Spokane. The next meeting will be held in Seattle, December 12 and 13.

**Prevention of Infant Mortality.**—The fourth annual meeting of the American Association for Study and Prevention of Infant Mortality was held in Washington, D. C., November 14-17, under the presidency of Dr. L. Emmett Holt, New York City. There were sessions on nursing and social work, pediatrics, obstetrics, eugenics, public school education for prevention of infant mortality, and vital and social statistics. The association elects its president a year in advance, and Mr. Homer Folks of New York City was elected for 1915. The president for the ensuing year is Dr. J. Whitridge Williams of Baltimore. The following other officers were elected: vice-presidents, Dr. M. J. Rosenau, Boston, and Miss Julia C. Lathrop, Washington; secretary, Dr. Philip Van Ingen, New York; executive secretary, Miss Gertrude Knipp, Baltimore (reelected), and treasurer, Mr. Austin McLanahan of Baltimore.

**Congress of Tropical Medicine.**—The third biennial congress of the Far Eastern Association of Tropical Medicine was held in Saigon, November 8-15, under the presidency of Dr. Clarac, inspector of the sanitary service in the colonial troops and inspector of sanitary and medical services of Indo-China. The work of the congress was divided in the following groups: (1) protozoology, helminthology; (2) cholera, plague, leprosy, tuberculosis; (3) tropical fevers (including paludism), beriberi, dysentery; (4) obstetrical surgery, infantile diseases; (5) climate, hygiene, sanitary regulations; (6) materia medica, pharmacology; (7) veterinary medicine, epizootics.

**Life Insurance Directors Elect.**—At the twenty-fourth annual meeting of the Association of Life Insurance Medical Directors of America, held in Philadelphia October 29 and 30, the following officers were elected: president, Dr. Edward K Root, Hartford, Conn., Aetna Life Insurance Company; vice-president, Dr. William Evelyn Porter, Mutual Life Insurance Company, New York City; secretary, Dr. Faneuil S. Weisse, Mutual Life Insurance Company, New York City (reelected); treasurer, Dr. Augustus S. Knight, Metropolitan Life Insurance Company, New York City (reelected).

**Tri-State Physicians Meet.**—At the thirtieth annual meeting the the Tri-State Medical Association of Mississippi, Arkansas and Tennessee, held in Memphis November 11-13, the following officers were elected: president, Dr. John Darrington, Yazoo City, Miss.; vice-presidents, Drs. William D. McCalipp, Yazoo City, Miss., Edward C. McDaniel, Tyronza, Ark., and Hiram B. Everett, Memphis, Tenn.; secretary, Dr. James L. Andrews, Memphis (reelected), and treasurer, Dr. James A. Vaughn, Memphis (reelected). Memphis was selected as the next place of meeting.

**Ohio Valley Physicians Meet.**—At the fifteenth annual meeting of the Ohio Valley Medical Association held in Evansville November 5 and 6, the following officers were elected: president, Dr. Argus D. Willmoth, Louisville; vice presidents, Dr. E. Otis Smith, Cincinnati, George M. Young, Evansville, and Dr. Joseph Rilus Eastman, Indianapolis, and secretary-treasurer, Dr. Benjamin L. W. Floyd, Evansville (reelected). It was decided to hold the 1914 meeting in Evansville.

**Colored Physicians Hold Meeting.**—At the annual meeting of the National Medical Association held in Nashville recently the following officers were elected: president, Dr. Arthur M.

Brown, Birmingham, Ala.; vice-presidents, J. M. G. Ramsey, Richmond, Va., and E. J. LeBranch, New Orleans; secretary, Dr. Walter G. Alexander, Orange, N. J., and treasurer, Dr. J. R. Levy, Florence, S. C. Raleigh, N. C., was selected as the place of meeting for 1914.

**Bequests and Donations.**—The following bequests and donations have recently been announced:

Michael Reese Hospital, Chicago, $20,000; Children's Memorial Hospital and Chicago Home for Convalescent Women, each $10,000; St. Luke's, Wesley, Mercy, Presbyterian, German, Englewood and Chicago Lying-in Hospitals, Chicago Visiting Nurses' Association and Home for Destitute Crippled Children, each $5,000, by the will of Edward Morris.

West Jersey Homeopathic Hospital, Camden, $11,000 by the will of the late Catherine C. Warner.

**Mission Board Asks Donations of Medical Equipment.**—The American Board of Commissioners for Foreign Missions has issued an appeal for surgical instruments of all practical kinds and in good condition, microscopes, sterilizers, etc., which are needed in the medical missions supported by the board in foreign countries. Any such instruments should be sent by parcels post to John G. Hosmer, 14 Beacon Street, Boston, Mass.

**Sanatorium Heads to Meet.**—The American Sanatorium Association will hold its ninth mid-winter meeting December 6 and 7, at the City of New York Tuberculosis Sanatorium, Otisville, as the guest of the Department of Health of New York, under the presidency of Dr. Vincent Y. Bowditch, Boston. The program includes the following important papers: "Some Desirable Features of a Large Municipal Sanatorium," by Herman M. Biggs, New York City; "Gastro-Intestinal Complications of Tuberculosis," by Dr. Charles W. Mills, Loomis, N. Y., and "Occupations for Afebrile Tuberculous Patients," by Dr. S. A. Knopf, New York City.

**Quarantine Regulations for Panama Canal.**—Orders have been issued by Colonel Goethals, promulgating the executive order of the President for the administration of the maritime quarantine regulations, to go into effect with the opening of the Panama Canal. These regulations apply to the entire Canal Zone. The bill of health that must be filled out and certified to by the masters of all vessels entering the canal, requires not only a complete description of the vessel, but a certificate as to the source of its food and water supplies, the sanitary history of the officers and crew and of the passengers, the sanitary history of the cargo and effects of those on board, the sanitary condition of the ship and a certification that none on board is ill of or has been exposed within two weeks to yellow fever, cholera, cholerine, small-pox, typhus fever, plague or leprosy.

## FOREIGN

**Medical Inspection of Schools in Belgium.**—The *Gazette Méd. Belge* of October 30 states that legislation is now pending to provide for medical inspection of all schools, public and private, the expense to be borne by the community. The organized profession asks for payment at the rate of 40 cents (2 francs) per pupil, but the question of remuneration has not yet been reached.

**Practicing Woman Physician in Berlin Receives Title of Professor.**—Dr. Rahel Hirsch, a woman physician in the great Charité Hospital of Berlin, has received the title of professor. This is the first time the title has been bestowed on a practicing woman physician in Germany. Besides Dr. Hirsch, there are only three women professors in Germany; one is professor of philosophy at Bonn and one in the State Musical College. The third is Prof. Lydia Rabinowitsch of Berlin, formerly assistant to Robert Koch. The work of Dr. Hirsch has been published mainly in the *Handbuch der Biochem.* and the *Charité-Ann.* and has dealt with the thyroid and internal secretions and the diseases connected therewith, over thirteen important articles having appeared since 1905. She has been at the Charité since her graduation in 1903, and is now 43 years old.

**Latin-American Medical Congress.**—The fifth international gathering of physicians from the various Latin-American countries was held at Lima, Peru, the first two weeks in November, with a large attendance. This meeting was at the same time the Sixth Pan-American Medical Congress. The invitation to hold the next meeting in Cuba was accepted. The special feature of the congress was the proof presented that the uta of Peru is due to a species of Leishmania. A report on the research leading up to this was published in THE JOURNAL, Nov. 8, 1913, p. 1713. *The Cronica Medica* of Lima, in honor of the congress, published a long historical review of medicine in Peru from the earliest Spanish invasion to the present time. From it we learn that some of the soldiers of Pizarro's command became affected with a disease which answers the description of Peruvian verruga as we know it now. The university of San Marcos was founded by a decree of the king of Spain in 1551, and the first hospital was founded in the same year. Regulations were passed in 1559 restricting the practice of medicine and surgery to men with proper credentials from Spain and two medical chairs were founded in 1635. The records state that rabies was not known in Peru before 1807.

**Dr. Grenfell's Work in Newfoundland and Labrador.**—Dr. Grenfell reached St. Johns, N. F., early in October, after a strenuous summer in the northern parts of Labrador. At a meeting at Government House the proposal was made and will be acted on to bind the various associations connected with his work in Newfoundland and Labrador into one common deed of incorporation, with a council of direction representing all. This shall bear the name of the International Grenfell Association and consist of two representatives from Newfoundland, two from New York, two from Boston and two from Canada. It is to meet in St. Johns each year in July and be responsible for the administration and financing of the whole work. Dr. Grenfell gave a summary of the work done in Newfoundland and in Labrador. He said that a hospital was maintained at St. Anthony at a cost of $25,000 a year, to which the Colonial government granted $1,500 yearly. From the first of January of the present year to the end of September there had been 3,160 out-patients and 352 in-patients, in charge of one surgeon and two nurses, with an eye and ear specialist and a dentist. At Forteau, at the end of Belle Isle Strait, on the boundary of the section of Labrador owned by Canada and Newfoundland, there is a small station with a nurse in charge but a medical man will locate there for the winter. This will be a great benefit to the people, as there are numerous small settlements every few miles. There is another hospital further west on the shore of the Gulf of St. Lawrence at Harrington. This is in Canadian territory and the Canadian Association care for it entirely. It is the only place from Quebec to Battle Harbor, a seaboard of several hundred miles, where a doctor resides, and he has calls at times from points hundreds of miles distant. In addition to these hospitals, Dr. Grenfell does an enormous amount of work himself on the hospital-ship *Strathcona* which has now been in service for thirteen years, and which was presented to the mission by Lord Strathcona. This attends to the requirements of 25,000 people on 1,200 fishing boats during five months of the year. At Battle Harbor on the Labrador coast is a hospital which costs annually $6,000. Two doctors and two assistants and four nurses are maintained there. At Indian Harbor, midway up the coast toward Hudson Strait, is still another hospital which costs $4,000 annually for maintenance, with a doctor and assistant and two nurses. The medical men at these hospitals are volunteers.

## CANADA

**Army Medical School.**—An army medical school has been established at Ottawa in connection with the Central Laboratory of Hygiene. Military medical officers will be trained in laboratory work and army sanitation.

**Proposed Amendment to Medical Act.**—The government of Alberta is considering an amendment to the medical act of that province in order to induce physicians to locate in the more thinly settled portions thereof. By it any medical men entering the province who are qualified to take the prescribed examinations will be granted an interim license, providing they are prepared to locate at least twenty miles from the nearest physician. When the examinations arrive, if candidates fail in one or more subjects they will have this interim license extended for six months in order to prepare for the subjects they failed to pass on.

**Hospital News.**—The ratepayers of Winnipeg recently refused to grant $275,000 for the purposes of the Winnipeg General Hospital. As less than three thousand persons voted out of a possible eighteen thousand the by-law will be resubmitted at the annual municipal elections in December.——Glace Bay, Cape Breton, is to have a new hospital at a cost of $80,000.——Fredericton, N. B., will enlarge Victoria Hospital.——Plans have been prepared for a tuberculosis hospital at St. John, N. B.——Walkerville, Ont., will erect a new hospital of fifty beds.——To complete the new Notre Dame Hospital in Montreal $750,000 is required.

**University News.**—Dr. John Stewart has been appointed professor of surgery in the Halifax Medical College, succeeding Dr. Norman McKay, resigned. In connection with this medical school the provincial government of Nova Scotia has just completed a new pathologic building; and a new building for the departments of chemistry and physics of Dalhousie University is being erected.——The Western University, London, Ont., requires a head for its physiological department. Dr. Paul S. McKibbin, for several years teacher in the Department of Anatomy in the University of Chicago, has been appointed professor of anatomy there.——The faculty of Queen's University, Kingston, has established three teaching fellowships, in anatomy, pathology and physiology.——At McGill University, Montreal, Dr. A. C. Geddes has succeeded Dr. Francis J. Shepherd as professor of anatomy. On account of the death of Dr. N. H. Alcock the department of physiology is without a head but the work is being carried on by the first assistant, Dr. Miller.

**Personal.**—Dr. Orton I. Grain, Selkirk, Man., member of the Manitoba Legislature, has resigned his seat in favor of the Hon. Dr. W. H. Montague of Winnipeg, who has been selected for minister of public works in the government of Manitoba. Dr. Grain has been appointed superintendent of Manitoba Indian Reserves.——Dr. Alexander J. Macauley has been appointed medical officer of health of Brockville, Ont.——Dr. Zephyr Rheaume has been appointed to the chair of experimental surgery just created at Laval University, Montreal.——Drs. Robert J. Blanchard and John S. Gray of Winnipeg were recently tendered a complimentary dinner by the medical staff of the general hospital of that city. Both medical men are retiring from active service after serving for a quarter of a century. Dr. James R. Jones presented Dr. Gray with a silver tea service and Dr. James W. Good made a presentation to Dr. Blanchard of a gold watch. Dr. Gray has been registrar of the College of Physicians and Surgeons for many years and Dr. Blanchard was president of the Canadian Medical Association in 1909. Dr. Gordon Bell presided at the function.

## LONDON LETTER

*(From Our Regular Correspondent)*

London, Nov. 1, 1913.

### A Tragedy of the Panel

An unfortunate event has occurred at the town of Wisbech in connection with the working of the insurance act. All the local physicians except two refused to work the act, and as two were not sufficient for the number of the insured persons a physician was imported for the purpose. This was resented by the local profession, who refused to meet him in consultation and boycotted him in every way. Feeling ran so high that he received three hundred anonymous abusive letters and post-cards, fifty on the day he arrived. His brass plate was repeatedly pulled down and defaced. He was repeatedly called on the telephone at night to distant cases which did not exist. But he became very popular with his patients and his practice became so large that he was overworked. Matters came to a crisis when at the instance of the president of the local branch of the British Medical Association he was arrested on the charge of criminal libel for sending an anonymous post-card. He emphatically denied the charge and bail was given. A few days later he did not get up at the usual hour and was found in his bed comatose. He died, evidently from narcotic poisoning; but whether he took the drug with suicidal intent or merely as a soporific has not yet been revealed. Public feeling in the town was aroused to an extraordinary extent. The people regarded his death as the result of persecution by the other physicians. A mass indignation meeting was held and after this crowds of workmen marched in procession to the house of the president of the local branch of the British Medical Association yelling and threatening violence if he showed his face. Stones were thrown at the windows and doors with destructive effect, and as each one crashed through the glass shouts of delight went up. After smashing all the windows and the front door the crowd marched to the house of another physician and smashed his windows. Extra police have had to be drafted into the town. Later a second attack was made on the house of the president, who telephoned for assistance from the police of the neighboring towns. All the time considerable damage was being done to his furniture. A daring attempt was made to rush his front door, which was barricaded, and shouts of "help him out! help him out!" came from the crowd. At this juncture the mayor arrived and attempted to read the riot act, but the attitude of the crowd was so threatening that he had to depart. Not until police reenforcements arrived could order be restored. The latest news is that the president has left the town for an unknown destination.

### The Falling Birth-Rate

An organization termed the National Council of Public Morals has appointed a birth-rate commission to report on the declining birth-rate. The chairman of the commission is Bishop Boyd Carpenter, and the members are composed of well-known clergymen, physicians and social workers. The inquiry is to be made in four directions: First, the extent and character of the decline are to be considered under such headings as the present British birth-rate and infantile mortality, general and classified according to income, occupation, province and county, urban and rural, and religion (if possible); statistics showing the proportion of sterile to total marriages (to find out whether smaller families or total childlessness is the cause of the fall), and foreign statistics showing the extent of declining birth-rates, special attention being paid to France and the Jews. Secondly, the alleged causes of the decline are to be investigated under the headings of physiologic causes (for example, the effect of town life, etc., on lateness of marriage, fertility and number of marriages), prudential motives and methods of restraint (moral, mechanical and chemical). Thirdly, the effects of the decline of the birth-rate, whether due to natural or to artificial causes, are to be searched out, under the headings of effects on the children, on the man and woman, on married persons and on home life. Fourthly, the economic and national aspects are to be dealt with, and the commission is to consider, for instance, the alleged results of a rapid increase of population in a country in which the land is fully cultivated, of a permanent surplus of workers on the condition of the working class (in the matter of unemployment, overcrowding, etc.) in the case of a declining or stationary population, and the alleged national danger of a disproportionate increase in other nations.

A discussion on the subject has taken place at Edinburgh under the auspices of the Scottish Council of Public Morals. Mr. James Marchant, the secretary of the National Council of Public Morals, read a paper. Among the explanations suggested by him for the fall in the birth-rate were the high standard of living, the love of pleasure and the higher education of women. A serious question was whether or not behind the lower birth-rate there was a lower degree of fertility. If if could be proved that only the weak and defective were ceasing to increase, there would be little cause for complaint; but apparently the fall ran through all classes. Dr. J. W. Ballantyne opened the discussion. A tremendous change had occurred, he said, in the vital statistics in the country, which was represented by the fall of the birth-rate from 35 to 25 per thousand. There was no doubt that the human race had begun to experiment on its reproduction, very much as it had in the past experimented on its digestion, and no one could foretell the ultimate result; but one immediate and welcome result had been the appreciation in the value of infant life which had followed the decrease in the number born. By this he thought it was possible to maintain an equilibrium so far as the number of lives in the nation was concerned.

### A Color Problem in India

Some time ago it was stated in a letter to The Journal that the government was adopting a new policy with regard to medical practice in India. Almost all the important civil medical appointments were held by the superior officers of the medical corps of the Indian Army, who are white men. It has been decided to throw these appointments open to the civil practitioners of India, who are mostly natives. This policy is now criticized by a society termed the European Defense Association, which has addressed a memorandum to the government on the subject. They point out that the European officials scattered all over India are seriously affected by the change. Hitherto they have been able to obtain skilled European medical aid for themselves, their wives and their families. The objection of European women to native medical attendants is well known. Moreover, the medical qualifications of the native physicians, at present at any rate, are of a lower kind than those of the European physicians.

## PARIS LETTER

*(From Our Regular Correspondent)*

Paris, Nov. 7, 1913.

### Death of Professor Jaboulay

A terrible railroad accident has occurred at Melun near Paris. Dr. Jaboulay, professor of clinical surgery at the Faculté de médecine de Lyon, was in one of two trains which crashed together. No news has been received from him, and all the evidence seems to indicate that his remains are among the débris which covers the scene of the catastrophe. Dr. Patel has been commissioned by the dean and professors of the Faculté de médecine de Lyon to search for and identify Dr. Jaboulay's body. Dr. Jaboulay was born in Saint Genis-Laval, July 3, 1860, and was appointed professor of clinical surgery in 1902.

### Prof. Charles Richet Recipient of the Nobel Prize

The Nobel prize for 1913 for medical science has been awarded to Dr. Charles Richet, professor of physiology at the Faculté de Médecine de Paris. He is the son of the celebrated surgeon, Alfred Richet, and was born in 1850. In 1887 he succeeded Béclard in the chair of physiology. Among his works the most notable is the discovery of anaphylaxis, for which the recent International Medical Congress at London awarded him the prize of Moscow. Professor Richet will probably be a candidate for the vacant seat in the Académie des Sciences left vacant in the section of medicine by the death of Dr. Lucas-Championnière.

## BERLIN LETTER

*(From Our Regular Correspondent)*

Berlin, Oct. 31, 1913.

### Personal

Professor Steyrer of Greifswald has been appointed director of the medical clinic at Innsbruck.

### Kaiser Wilhelm Institute for Experimental Therapy

October 28 the Kaiser Wilhelm Institute, which was founded by the kaiser and is to be conducted under his protection, was opened in the presence of the royal family. The state provided the ground, and the Kaiser Wilhelm fund the material for the building. The cost of the institute was about 500,000 marks ($125,000). In the main building is the serologic department, which is conducted by the director of the institute, Professor Wassermann, and the department of chemistry, headed by Professor Neuberg, formerly assistant of Professor Salkowski. There is a room for dangerous explosives and also a special room for a large centrifuge are in the basement. The lid of the centrifuge is of glass in order that should there be a break in the centrifuge the pieces may easily be thrown outside. A separate department is available in which animals may be observed as to their health before use. This building is available for large animals such as horses and cows. Besides this there is a larger building of two stories in which are conducted experiments on animals. In front of the animal stables there are exercising-yards for the animals separate from the stables mentioned, and in another department are a kitchen for preparing food, a room for drawing blood from horses in order to obtain serum, and two complete aseptic operating-rooms for larger animals.

# *Marriages*

Randolph Macon Grimm, M. D., U. S. P. H. S., Savannah, Ga., to Miss Heloise Percifull of Nesting, Va., November 5.

Joseph Redmond Condon, M.D., Des Moines, Ia., to Miss Margaret Lauretta Byrne of Chicago, November 12.

Joseph Abel Thibodeau, M.D., Madison, Me., to Miss Arthemese Gauthier of Rumford, Me., November 2.

Olive Violet Brasier, M.D., Butte, Mont., and Harney M. Cardua of Washington, D. C., November 2.

Reuben Spencer Simpson, M.D., to Miss Tusanelda Nusbickel, both of Lyons, N. Y., November 4.

Ira David Baxter, M.D., Spencerville, Ohio, to Miss Sue Wager of Delphos, Ohio, November 4.

James Augustus Longo, M.D., to Miss Josephine McMahon, both of Sheppton, Pa., November 5.

Oscar Cleff, M.D., Chicago, to Miss Zolier Jacqueline Parsons of Mansfield, La., Nevember 5.

Robert H. Townsley, M.D., Wagner, S. Dak., to Miss Maude E. Beverly of Sioux City, Ia.

Urial McReynolds, M.D., to Miss Ruby Murphy, both of Knox City, Mo., October 30.

Gilbert H. Wynekoop, M.D., to Miss Lucile Megahan, both of Chicago, November 20.

Edward James Monahan, M.D., Revere, Mass., to Miss Anna Olive Thompson, of Prince Edward Island, at Milton, Mass., November 11.

# *Deaths*

**Ira Kilbourn Gardner, M.D.** University of Michigan, Ann Arbor, 1870; a Fellow of the American Medical Association; vice-president of the National Association of Railway Surgeons; chairman of the Board of Councilors of the Iowa State Medical Society, and secretary-treasurer of the Chickasaw County Medical Society; local surgeon of the St. Paul system at New Hampton, Ia.; president of the Board of Education; died at his home in New Hampton, November 4, from cerebral hemorrhage, aged 67.

**Alfred J. Pedlar, M.D.** Cooper Medical College, San Francisco, 1877; in 1877 chairman of the Board of City Trustees and physician of Fresno County, and a member of the City Board of Health; for several years acting assistant surgeon U. S. Army with service during the Spanish-American War as post surgeon at the Presidio of San Francisco; from 1877 to 1907 a practitioner of Fresno and for two terms state senator; died at his home in Alameda, Cal., from asthma, aged 59.

**Thomas Wistar, M.D.** University of Pennsylvania, Philadelphia, 1859; for thirty-nine years chief medical inspector and medical director of the Provident Life and Trust Company, Philadelphia; for several years secretary of the Philadelphia Dispensary; a member of the staff of the Wills Eye Hospital, and a director of the Wistar Institute of Anatomy; died at his home in Philadelphia, September 27, from heart disease, aged 77.

**John Erskine Taylor, M.D.** Medical College of Philadelphia, 1890; a Fellow of the American Medical Association; formerly president of the Venango County (Pa.) Medical Society; a member of the American Association for the Advancement of Science, the American Association of Life Insurance Examining Surgeons, and the Oil City Medical Club; died at his home in Nickelville, October 30, from pulmonary tuberculosis, aged 53.

**Henry W. Nelson, M.D.** Homeopathic Hospital College, Cleveland, Ohio, 1865; College of Physicians and Surgeons, Keokuk, Ia., 1876; Jefferson Medical College, 1880; at one time secretary of the Jefferson County (Ohio) Medical Society; for nearly fifty years a practitioner of Steubenville; died at the home of his daughter in Milwaukee, September 25, from the effects of an overdose of morphin, aged 76.

**Richard French Stone, M.D.** University of Pennsylvania, Philadelphia, 1865; formerly surgeon general of Indiana National Guard, professor of materia medica, therapeutics and clinical medicine in the Central College of Physicians and Surgeons, Indianapolis, and president of the Marion County Medical Society; died in his office in Irvington, Indianapolis, October 3, from accidental gas asphyxiation, aged 69.

**Aria Louis Derdiger, M.D.** College of Physicians and Surgeons, Chicago, 1903; a Fellow of the American Medical Association; assistant in bacteriology in his alma mater; professor of psychiatry and ophthalmology in the Chicago College of Medicine and Surgery; president of the Chicago Eye, Ear, Nose, and Throat Infirmary; died at his home in Chicago, November 12, aged 47.

**Walter J. Pennell, M.D.** University of Vermont, Burlington, 1891; a Fellow of the American Medical Association and a specialist on diseases of the eye, ear, nose and throat; ophthalmic and aural surgeon to the Central Maine General Hospital; oculist and aurist to Bates College; died at his home in Auburn, October 29, from cerebral hemorrhage, aged 50.

**James Seaton Wise, M.D.** Medical College of Ohio, Cincinnati, 1863; L. F. P. S. Glasgow, and L. R. C. P. Edinburgh, 1868; a Confederate veteran; for several years a surgeon on transatlantic steamers; for two terms coroner of Kenton County, Kentucky; died in his home in Covington, October 12, from cerebral hemorrhage, aged 72.

**John Sidney Warren, M.D.** Jefferson Medical College, 1866; assistant surgeon of the Eighth U. S. Colored Horse Artillery during the Civil War; of New York City; a member of the New York Academy of Medicine, and for fifteen years treasurer of the New York County Medical Society; died in Atlantic City, N. J., July 18, aged 72.

**Joseph William Posthauer, M.D.** College of Physicians and Surgeons, New York City, 1895; of Boston; formerly associate professor of physiology in Milwaukee Medical College; for many years a practitioner of Boston and later of Auburndale, Mass.; died at his home in Burlington, Vt., September 22, from pleurisy, aged 40.

**Edward H. Higbee, M.D.** Missouri Medical College, St. Louis, 1884; a member of the Illinois Medical Society; one of the founders of the Polyclinic Hospital, St. Louis; surgeon for the Chicago and Alton Railroad at Roodhouse, Ill., and alderman for several years; died at his home, November 3, from pneumonia, aged 66.

**William Theodore Wenzel, M.D.** Cooper Medical College, San Francisco, 1876; one of the founders of the San Francisco College of Pharmacy and professor of chemistry for many years; chemist to the United States Appraisers' Stores, San Francisco for fourteen years; died at his home in that city, July 31, aged 84.

**Joseph D. Crum, M.D.** Eclectic Medical Institute, Cincinnati, 1881; a member of the Michigan State Medical Society; for thirty years a practitioner of Owosso, Mich., and for several terms a member of the board of education; died at the home of his son in Kalamazoo, November 1, from nephritis, aged 60.

**Amy Hamm Brush Clark, M.D.** Woman's Medical College of the New York Infirmary for Women and Children, New York City, 1884; a member of the Medical Society of the State of Pennsylvania; a member of the staff of the Samaritan Hospital; died at her home in Philadelphia, November 4, aged 54.

**Joseph Augustus Stites, M.D.** Bellevue Hospital Medical College, 1875; for nine years surgeon of the Netherlands American Steam Navigation Company, and later health officer and medical inspector in Springfield, N. J.; died in his home in that place, October 23, from cerebral hemorrhage, aged 61.

**James D. Van Derveer, M.D.** College of Physicians and Surgeons, New York City, 1866; for several years commissioner of deeds at North Branch, N. J., and prior to that time a practitioner of Liberty Corner, N. J.; died at his home in North Branch, July 29, from heart disease, aged 75.

**George W. Jenkins, M.D.** New York University, New York City, 1851; a member of the State Medical Society of Wisconsin; for many years local surgeon of the Chicago, Milwaukee and St. Paul Railway at Kilbourn, Wis.; died at his home, November 3, from senile debility, aged 89.

**Alexis Marcy Leon, M.D.** College of Physicians and Surgeons, New York City, 1878; a Fellow of the American Medical Association; visiting physician to St. Francis' Hospital, New York City; died suddenly at his home in New York City, November 2, from heart disease, aged 56.

**Orbun T. Moore, M.D.** Washington University, St. Louis, 1875; for many years a practitioner of St. Louis and formerly chief diagnostician of the St. Louis Board of Health, who recently moved to Augusta, Mo.; died in St. Charles, Mo., October 22, from heart disease, aged 64.

**Arthur F. Niedermeier, M.D.** University of Pennsylvania, Philadelphia, 1900; chief medical examiner and surgeon at the Pennsylvania Railroad Terminal, New York City; died in Mercer Hospital, Trenton, N. J., October 23, from septicemia due to an operation wound, aged 37.

**Robert Henry Reynolds, M.D.**, Eclectic Medical Institute Cincinnati, 1872; for forty years a practitioner of Huron County, Ohio; died at his home in Greenwich, September 20, from cerebral hemorrhage, aged 67.

**Henry Nathan Longfellow, M.D.** Harvard Medical School, 1904; a Fellow of the American Medical Association, and a member of the dermatological staff of Mt. Sinai Hospital, Boston; died at his old home in Georgetown, Mass., October 31, from Hodgkin's disease, aged 42.

**Mordecai M. McDowell, M.D.** Hospital College of Medicine, Louisville, Ky., 1878; a member of the Indiana State Medical Association; at one time sheriff of Knox County, Ind., and a member of the state senate; died at his home in Vincennes, November 9, aged 68.

**William A. Holloway, M.D.** University of Alabama, Mobile, 1889; a Fellow of the American Medical Association and an esteemed practitioner of Goodwater, Ala.; was assaulted November 4 and died at his home a few hours later, aged 46.

**William H. Schenk, M.D.** New York University, New York City, 1848; for many years a practitioner of Australia and later of his native place, Flemington, N. J.; died September 27, aged 87, in the house in which he was born.

**G. A. Niedermeyer, M.D.** Medical College of Ohio, Cincinnati, 1861; assistant surgeon of the Twenty-Seventh Colored U. S. Volunteer Infantry during the Civil War; died at his home in Cincinnati, October 20, aged 76.

**Ray McKennedy Van Cleave, M.D.** Indiana University School of Medicine, 1911; of Muncie, Ind.; was found dead in a hotel in Terre Haute, Ind., September 7, from the effects of poison believed to have been self-administered with suicidal intent, aged 28.

**Samuel Matthew Crawford Howell, M.D.** Atlanta, (Ga.) Medical College, 1891; a Fellow of the American Medical Association; president of the First National Bank of Midland City, Ala.; died at his home, October 30, from cerebral hemorrhage, aged 44.

**William Wright Markoe, M.D.** Yale University, New Haven, Conn., 1898; a Fellow of the American Medical Association; acting assistant surgeon U. S. P. H. S., with recent station at Ft. Stanton, N. Mex.; died in Charleston, N. H., October 19, aged 39.

**David R. Springsteen** (license, Iowa, years of practice, 1886); a veteran of the Civil War, and for more than thirty years a practitioner of Weldon and Decatur City; died at his home in the latter place, September 23, from heart disease, aged 69.

**Samuel Adams Robinson, M.D.** Homeopathic Hospital College, Cleveland, 1858; formerly of New York and Portland, Ore.; well known as a public welfare worker; died in his apartment in Washington, D. C., October 9, from heart disease, aged 75.

**August Schumacher, M.D.** Medical College of Ohio, Cincinnati, Ohio, 1897, once health officer of Hamilton, Ohio, and for four years coroner of Butler County; died at his home in Hamilton, October 16, from aneurysm of the aorta, aged 39.

**Lindsay P. O'Neal, M.D.** Washington University, Baltimore, Md., 1865; surgeon of volunteers during the Civil War; for several terms a member of the common council of Mechanicsburg, Pa.; died at his home, September 18, aged 74.

**Samuel Miller Mosgrove, M.D.** Miami Medical College, Cincinnati, 1872; Bellevue Hospital Medical College, 1873; formerly a member of the Ohio State Senate; died at his home in Urbana, October 22, aged 62.

**N. H. Palmer, M.D.** University of Arkansas, Little Rock, 1911; formerly of Crossett and Portland, Ark.; died in Delta, Colo., September 20, from tuberculosis of the lungs, aged 31.

**Absalom Pearson, M.D.** Cincinnati College of Medicine and Surgery, 1880; health officer of New Weston, Ohio; died at his home, August 6, from pulmonary hemorrhage, aged 75.

**DeWitt H. Thomas, M.D.** University of Tennessee, Nashville, 1887; local surgeon for the Illinois Central Railroad at Sturgis, Miss.; died at his home in that place, October 11.

**John Nelson Merrill, M.D.** University of Michigan, Ann Arbor, 1869; a member of the Maine Medical Association; died at his home in Skowhegan, October 2, aged 71.

**James H. Snowden** (license, Arkansas, 1903); for many years an eclectic practitioner of Conway County; died at his home in Center Ridge, September 30, aged 65.

**Philip D. Reefy, M.D.** Eclectic Medical Institute, Cincinnati, 1869; Western Reserve University, Cleveland, 1871; died at his home in Elyria, Ohio, October 7, aged 69.

**Andrew W. Meyers, M.D.** University of Tennessee, Nashville, 1885; died at his home in Scottsville, Ky., October 13, from typhoid fever, aged 57.

**Dennis M. Smith, M.D.** Albany (N. Y.) Medical College, 1888; examiner in lunacy; died at his home in Cambridge, N. Y., October 5, aged 66.

**Frank A. Nevers, M.D.** Missouri Medical College, St. Louis, 1874; died at his home in Houlton, Me., August 3, from arteriosclerosis, aged 63.

**William Harvey Kincaid, M.D.** Memphis Hospital College, 1900; died at his home in McKinney, Tex., September 17, from typhoid fever, aged 37.

**Thomas W. Moore, M.D.** Tulane University, New Orleans, 1894; died in his office in Lagrange, Tex., September 28, from heart disease, aged 42.

**Charles H. Shadle, M.D.** University of Pennsylvania, Philadelphia, 1894; of Templeton, Pa.; died in Springboro, from pneumonia, aged 44.

**Edward Arthur Wheaton, M.D.** Ohio Wesleyan University, Cleveland, 1897; died at his home in Mansfield, Ohio, September 25, aged 48.

**Omar E. Newman, M.D.** Western Reserve University, Cleveland, 1878; died at his home in Penn Yan, N. Y., October 7, aged 58.

**Arthur D. Raines, M.D.** St. Louis College of Physicians and Surgeons, 1898; died in his office in St. Louis from a gunshot wound of the head, self-inflicted, it is believed with suicidal intent, September 29, aged 38.

**John M. Rader, M.D.** St. Louis College of Physicians and Surgeons, 1893; formerly deputy coroner of St. Louis County; died at his home in St. Louis, October 22, from cerebral hemorrhage, aged 55.

**Nathan J. Saunders, M.D.** College of Physicians and Surgeons, Kansas City, Kan., 1890; a Fellow of the American Medical Association; died at his home in Glen Elder, Kan., October 25, aged 52.

**Ray DeWitt Robinson, M.D.** Cleveland Homeopathic Medical College, 1903; of Akron, Ohio; died in Grace Hospital, Cleveland, October 7, two days after an operation for appendicitis, aged 44.

**Harry Luther Towner, M.D.** Chicago Homeopathic Medical College, 1879; for many years a practitioner of Sayre, Pa.; died at the home of his daughter in New York City, October 5, aged 63.

**Robert Wadsworth, M.D.** Hahnemann Medical College, Philadelphia, 1876; of Rochester, N. Y.; while making a professional call in that city October 17, died from angina pectoris, aged 63.

**T. F. Wynn, M.D.** Memphis Hospital Medical College, 1893; of Denison, Tex.; died in that city, July 20, two months after a fall in which he struck his head on a cattle-guard, aged 51.

**L. V. White, M.D.** Southern Medical College, Atlanta, 1886; for more than twenty years a practitioner of Brewster County, Texas; died at his home in Marathon, September 29.

**Henry Westerman** (license, Minnesota, 1887); for more than half a century a practitioner; died at his home in Mankato, October 14, from disease of the stomach, aged 86.

**James White, M.D.** University of Toronto, Ont., 1875; first president of the Hamilton Medical Association; died at his home in Hamilton, Ont., August 17, aged 55.

**Stephen G. Warren, M.D.** Cleveland University of Medicine and Surgery, 1865; died at his home in Attica, N. Y., October 17, from cerebral hemorrhage, aged 73.

**William B. Zineman, M.D.** Baltimore University, 1896; a well-known optician of Philadelphia; died at his home October 15, after a long illness, aged 49.

**George Victor Winter, M.D.** Northwestern University Medical School, Chicago, 1911; of Albany, Minn.; died in St. Paul, July 25, from appendicitis, aged 33.

**William W. Watkins, M.D.** Tulane University, New Orleans, 1872; a wealthy banker and planter of Aberdeen, Miss.; died at his home, September 30, aged 63.

**J. M. Condon, M.D.** Medical College of Ohio, Cincinnati, 1881; of Scranton, Pa.; died in the Scranton State Hospital, September 14, aged 56.

**John Savage Wade, M.D.** University of Nashville, Tenn., 1878; died at his home in Weston, Tex.; August 7, from locomotor ataxia, aged 65.

**Edward Everett Gilbert, M.D.** University of Louisville, Ky., 1886; of Haskell, Tex.; died about October 8, from cerebral hemorrhage, aged 53.

**George Batchelder Langmaid, M.D.** Boston University School of Medicine, 1877; died at his home in East Greenwich, R. I., September 14, aged 65.

**Lucian Beauregard Horton, M.D.** Louisville (Ky.) Medical College, 1890; died at his home in Gate City, Va., September 26, aged 52.

**Frederick R. W. Warren, M.D.** Queen's University, Kingston, Ont., 1905; of Assiniboia, Sask., died September 1, aged 36.

**Aaron Mason Larkin, M.D.** University of Vermont, Burlington, 1868; died at his home in Norwood, N. Y., August 21, aged 71.

**Alfred Helton** (license, years of practice, Indiana, 1902); died at his home in Paynetown, August 7, from heart disease, aged 62.

**Robert M. McGary, M.D.** Jefferson Medical College, 1884; died suddenly at his home in Mechanicsburg, Pa., September 1.

**Robert C. Mayes, M.D.** University of Louisville, Ky., 1872; died at his home in Brownwood, Tex., October 19, aged 76.

**William L. Garratt** (license, years of practice, Michigan, 1900); died at his home in Watervliet, October 10.

# The Propaganda for Reform

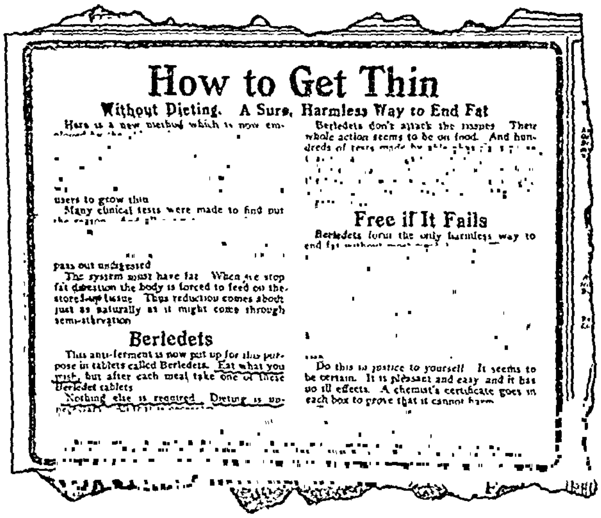
In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

## BERLEDETS

### Another Fraudulent and Dangerous Obesity Cure

So long as many well-to-do women continue to eat much and exercise little, so long will they be likely to become obese. So long, also, as the present style in women's fashions calls for the svelt figure, so long will the exploiters of fraudulent "obesity cures" become rich. Every "fat cure" of this type emphasizes in its advertisements two things: first, that those who use it need not diet; second, that they need not exercise. Berledet tablets are one of the latest fake cures for obesity, and they run true to form in that they are sold under the claim that neither dieting nor exercise is necessary to reduce weight when Berledets are used.

Several inquiries have been received regarding the product; one, in particular, came from a layman of more than average intelligence, who complained that his wife after taking this stuff had become seriously ill and had to be put under a physician's care. Here are some of the advertised claims:



How to Get Thin

Without Dieting. A Sure, Harmless Way to End Fat

Here is a new method which is now em-

users to grow thin

Many clinical tests were made to find out

pass out undigested

The system must have fat. When we stop fat digestion the body is forced to feed on the stored-up tissue. Thus reduction comes about just as naturally as it might come through semi-starvation.

Berledets

This anti-ferment is now put up for this purpose in tablets called Berledets. Eat what you wish, but after each meal take one of these Berledet tablets.

Nothing else is required. Dieting is un-

Berledets don't attack the tissues. Their whole action seems to be on food. And hundreds of tests made by able

Free if It Fails

Berledets form the only harmless way to end fat without

Do this in justice to yourself. It seems to be certain. It is pleasant and easy and it has no ill effects. A chemist's certificate goes in each box to prove that it cannot harm.

A typical Berledets advertisement.

> "Eat what you wish, but after each meal take one of these Berledet tablets. Nothing else is required. Dieting is unnecessary."
>
> "*Berledets form the only harmless way to end fat without the most rigid dieting.*"
>
> "A chemist's certificate comes in each box to prove that it cannot harm."
>
> "In our estimation, this discovery has settled forever the problem of obesity."

Like every fraudulent obesity cure, the claims made for the stuff before you purchase it differ from those made in the instructions that come with the dollar package. While the advertisement specifically states that Berledets will make you thin "without dieting," the instructions with the preparation urge:

> "Moderation in the use of fat-forming food."
>
> "Eat sparingly of rich gravies, pastries, butter and fresh breads. Also of fried foods."

While, too, the newspaper advertisements intimate that no exercise is necessary to reduce obesity if Berledets are used—"nothing else is required"—yet, *after the dollar has been paid*, the purchaser finds that it is necessary to:

> "Exercise freely in the open air."

The chemist's report referred to in the advertising matter sent out with the package, reads as follows:

## VEROFORM GERMICIDE OMITTED FROM N. N. R.

### Report of the Council on Pharmacy and Chemistry

Veroform Germicide is described in New and Nonofficial Remedies, 1913, as a solution produced by dissolving formaldehyd gas in a solution of soap. It is claimed to contain 20 per cent. of formaldehyd. The claimed germicidal action of this preparation appearing improbable in the light of the investigations of disinfectants made by the Hygienic Laboratory of the U. S. Public Health Service, the owners of Veroform Germicide were asked to substantiate their claims. Such evidence not having been produced, the council voted that Veroform Germicide be omitted from future editions of New and Nonofficial Remedies. The report which appears below was submitted to the manufacturer, and after some months' waiting, was authorized for publication.

W. A. Puckner, Secretary.

On October 8, 1912, the report of the Hygienic Laboratory of the United States Public Health Service on commercial disinfectants showing Veroform Germicide to have a phenol coefficient (without organic matter) of but 0.43, was called to the attention of the Veroform Hygienic Company, with the suggestion that a product which has a germicidal value less than that of phenol should probably not be called a germicide. In reply the firm wrote, on Oct. 11, 1912, that ". . . we will have an investigation made and will advise you in detail." This information has not been received and the last letter, dated Dec. 27, 1912, reminding the firm of its promise that the question in dispute would be investigated, brought no reply.

Besides the questionable claim that Veroform is a germicide the direct claim is made that, although less poisonous, "Veroform Germicide . . . has a more bactericidal effect" than carbolic acid. This claim is not substantiated by the Hygienic Laboratory, which found a coefficient of 0.43. Under the circumstances the claim for Veroform Germicide is unwarranted and in conflict with the rules of the council. It is therefore recommended that Veroform Germicide be omitted from New and Nonofficial Remedies, and that publication of this report be authorized.

# *Association News*

## THE ALLEGED DECISION AGAINST THE AMERICAN MEDICAL ASSOCIATION

There have appeared recently in the public press and in a number of medical journals interviews and letters purporting to have emanated from Dr. G. Frank Lydston, in which it is claimed that he had won a very important decision in the Appellate Court against the American Medical Association;[1] that the American Medical Association was, and has been, acting illegally for several years; that the trustees are illegally holding office and that all of the acts which have been done by the trustees are illegal. As these statements are untrue, the Board of Trustees, at its meeting Nov. 7, 1913, authorized that the facts be published for the information of those members of the Association who are not familiar with them.

As is well known, for a long time Dr. Lydston has carried on a wordy warfare against the association and its officers. We are informed that for several months prior to January, 1911, he and his attorney endeavored to induce the state's attorney of Cook County to file a petition for a mandamus against the trustees of the association, claiming that they were illegally elected. The state's attorney, after investigating the subject, decided that there was no case against the association and declined to bring the suit. The matter was then taken to the attorney-general of the state of Illinois, who likewise declined to bring the suit.

Jan. 5, 1911, he filed a petition in the Circuit Court of Cook County *against the state's attorney* of that county *praying that the latter be compelled to commence an action of mandamus against the trustees and the association.* To this petition the state's attorney filed a demurrer, which in legal effect is making an issue on the petition as filed to the effect that granting all that is stated in the petition to be true, there is yet no cause of action. No proof or evidence of any kind is offered or received on such an issue. A lengthy hearing was had on the demurrer, and the judge sustained the same and dismissed the petition. From that decision an appeal was prayed but was not perfected.

April 28, 1911, a new petition was filed *against the state's attorney*, which petition was more elaborately drawn than the first one, and again the state's attorney filed a demurrer to the same. Another lengthy hearing was had on this demurrer, and again the judge sustained the demurrer and dismissed the appeal. An appeal was perfected to the Appellate Court, which court consists of three judges sitting as a reviewing court. Arguments were made in that court, and on Oct. 9, 1913, by a divided court, the finding of the judges below was reversed by the opinion of two judges, one judge dissenting. From this decision an appeal has been prayed by the state's attorney and allowed to the Supreme Court of Illinois, where the cause is now pending.

As will be seen, the decision does not in any way affect the American Medical Association, but relates entirely to the duties of the state's attorney. Should the Supreme Court sustain the decision of the Appellate Court all it would mean would be that the state's attorney would have to bring quo warranto proceedings against the American Medical Association. Then, and not till then, would the American Medical Association be technically concerned, and not until then would the question come up as to the association's method of transacting its business. It will be seen that the statements and inferences contained in the interviews and articles above mentioned, that Dr. Lydston had won a great decision over the American Medical Association, are without foundation in fact.

There has never been the slightest doubt or question on the part of counsel but that every act of the association has been perfectly legal, and in every way in conformity with the statute of the state and decisions of the courts.

Board of Trustees of the American Medical Association,
W. T. Councilman, *Chairman*,
M. L. Harris, *Secretary*.

### Unreliable Wassermann Reactions

*To the Editor:*—My purpose in this note is to emphasize the mistakes, sometimes wretched in their consequence, that are being made in the interpretation of the serum-complement reaction for syphilis. The occasion for it is in the following experience:

A few days ago a young woman of the best type—attractive, intelligent, educated, sensitive, virtuous—came in to me from her physician to see if she had syphilis. During her menses six weeks before she had had a confusing rash, which had recurred, and blood had been sent to a laboratory at a distance to see if the eruption could possibly be that of syphilis. A positive reaction had been reported and a diagnosis of syphilis made from the laboratory. Her physician had sent her to me because, in his own words, he could not believe it. All of the facts were against the diagnosis; there was no history and there were no symptoms of syphilis. She had an eruption which in my opinion could be definitely said not to be syphilis, and this was also the independent opinion of my associate, Dr. A. W. Stillians. I gave blood for a Wassermann to my assistant and sent some also to Dr. F.

---

[1] The point at issue is whether or not a corporation organized "not for profit" comes under the law of Illinois governing joint stock corporations: specifically whether it is necessary to hold meetings in Illinois for the election of officers. The question is one that affects all similar associations, as for instance the American Pharmaceutical Association, National and Retail Druggists, several fraternal societies, etc.

G. Harris, without intimating to either of them what result I expected. Each, independently, reported a negative reaction. The woman did not have syphilis.

The bald recital of the facts gives no intimation of the tense misery of the situation. Here was a guiltless young unmarried woman—worthy to be the wife or daughter of one of the best of us—whose life seemed to her and her family to be blasted by syphilis, and who might have gone to her dying day with the conviction that she had syphilis, if her doctor had not been unwilling to accept as final a Wassermann report that had been offered as final evidence. The only way to realize the horror of such a situation is to try to imagine the patient one of the innocent women of one's own family.

This is not a unique case in my experience; I have had several of this character. I know at least two syphilophobes who are going about in constant fear lest they have syphilis, because of mistaken diagnoses of syphilis based on unreliable Wassermanns. And the sometimes appalling character of these mistakes of a positive Wassermann in the absence of syphilis impels me to call attention to them.

Undoubtedly a good many unreliable Wassermanns are being made. The greatest fault is carelessness in technic. Another source of error is old blood. Blood two days old, even when kept in an ice-box, is unreliable for the test; and much more so if it has been kept at car temperature while in transit to a distant laboratory. Finally, some careful and conscientious but overzealous workers are drawing their test so fine in order to increase its sensitiveness that their readings sometimes become unreliable.

This criticism is not directed against the Wassermann as a test. The Wassermann is all right, but it should be appreciated that it is open to error in manipulation. It is not final and unimpeachable evidence, and in improbable cases, like the one mentioned, a positive reaction should not be accepted as final unless one can be perfectly sure of the reliability of the process by which it has been obtained. The tendency to accept the result of a test as infallible is the old story of allowing too much weight to laboratory findings—as though they were above the common human frailty of error. The Wassermann reaction is but one fact in the diagnosis of syphilis. It should be confirmed by other diagnostic evidence. In the very rare absence of this, it is not too much caution to have two independent tests to check each other.

WILLIAM A. PUSEY, M.D., Chicago.

## The Paramecium as an Indicator of Pathologic Tissue Changes

*To the Editor:*—The editorial on the work of Underhill and Woodruff (THE JOURNAL, Nov. 8, 1913, p. 1720), is justified in every way. At the suggestion of Herbert Spencer Jennings of Johns Hopkins and under his guidance, about a year ago I began an investigation of the sudden development of epidemics among paramecia. Every now and again a race of *Paramecium caudatem* or *Paramecium aurelia* will lose its normal powers of multiplication. A division-rate of eight or sixteen a day may suddenly cease, and the race of paramecium may become almost sterile for a day or two and then be annihilated.

We have found many of these differences in division-rate and destruction to be due to specific bacterial troubles, such as the overgrowth of zooglea masses of putrefying organisms of the *B. proteus* group, the *B. turgidus* and the like. Of course, the many racial and environmental accidents that produce acute changes in the rate of division of paramecia are too numerous to allow the deduction to be made that this can be used as an indicator of pathologic tissue change.

LEONARD K. HIRSHBERG, M.D., Baltimore.

---

**Rest in the Treatment of Heart-Disease.**—And last, but not least, rest. I say "last, but not least, rest," and I am always tempted to utter the paraphrase: "Now abideth diet, drugs, rest, these three, but the greatest of these is rest."—F. J. Wethered, in (London) *Clinical Journal.*

# Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

### USES OF CHROMIUM SULPHATE IN MEDICINE

*To the Editor:*—Please enlighten me about the claims made for chromium sulphate. M. E. M.

ANSWER.—An answer to a similar query was published in THE JOURNAL, Feb. 4, 1911, p. 367.

In his article published in the *Monthly Cyclopedia and Medical Bulletin*, September, 1908, Dr. S. Kolipinski said, "At the annual meeting of the American Therapeutic Society, May, 1902, the writer read a concise paper on the 'Therapeutics of Chromium Sulphate.' As far as he knows, the statements there made have not been confirmed, nor has this chemical attracted attention as a medicine."

Dr. Kolipinski also said, "The diseases in which chromium has been used with success are: cirrhosis of the female breast, castration, menopause, functional impotency in men, chronic alcoholism, nervous vomiting and vomiting in pregnancy, neurasthenia, locomotor ataxia, exophthalmic goiter and the migraines."

Since that time no literature has appeared on this subject, except as noted before, and the firm which puts out the preparation of chromium sulphate still uses Dr. Kolipinski's paper as practically its sole advertising matter. There is no doubt that the substance has been tried by clinicians who have failed to obtain satisfactory results. If this were not the case, reports of its use would have appeared in reputable medical journals before this time. It seems evident, therefore, that this substance has failed to satisfy the remarkable claims made for it by its introducer.

### INFORMATION CONCERNING VARIOUS TESTS

*To the Editor:*—Please tell me where I can find a thorough description and information of how to make the following tests:

1. Lange's test of cerebrospinal fluid in congenital syphilis.
2. Complement-fixation test for gonorrhea.
3. Abderhalden's test for pregnancy.
4. Tschernogubow's blood-test for syphilis.
5. Kowarski's blood-test for differential diagnosis of diabetes.

W. E. MCKINLEY, M.D., Grant City, Mo.

ANSWER.—1. See "A Manual of Venereal Diseases," by Keogh, Melville, Leishman, Pollock and Harrison, p. 126.

2. See THE JOURNAL, Oct. 5, 1912, p. 1309. A description of the method is given by Lespinasse and Wolff, *Illinois Med. Jour.*, January, 1913, p. 26.

3. See THE JOURNAL, Sept. 6, 1913, p. 788.

4. Tschernogubow's test for syphilis is described in THE JOURNAL, April 2, 1910, p. 114, by W. J. Butler.

5. Kowarski's method of testing for sugar in the urine is a modification of the phenylhydrazin test. It consists in mixing 5 drops of pure phenylhydrazin in a test-tube with 10 drops of acetic acid, gently shaking and then adding about 1 c.c. of a saturated solution of sodium chlorid. To the solid mass that forms is added from 3 to 5 c.c. of the urine, and the test-tube is then heated in the free flame for two minutes after its contents begin to boil. On cooling, the osazone crystals separate from urines containing over 2 per cent. of sugar in one minute, and from weaker solutions in about five minutes. It will be noted that this method is merely a test for sugar and not for differential diagnosis of diabetes.

### RABIES AND THE PASTEUR TREATMENT

*To the Editor:*—I wish to raise the following questions:

1. Are there not more cases of rabies in [illegible] now than before the Pasteur treatment becar[illegible]
2. Is there not a greater death-rate [illegible]ients now than before the Pasteur treatment became popular?
3. Is the fatality among Pasteur-treated patients about 8 per cent.?
4. What would be the death-rate of dog-bitten patients minus the Pasteur treatment?

L. G. LELAND, M.D., Newton Falls, Ohio.

ANSWER.—1. The work of Pasteur did not result in an increase in the number of cases of rabies in dog-bitten patients. He drew the attention of the medical profession and the laity to the disease, which had been comparatively neglected up to that time. Since the Pasteur treatment became popularized, cases of rabies have been recognized, which accounts for any apparent increase there may be in their number.

2. Before Pasteur's studies on rabies, statistics concerning this disease were very incomplete, difficult to obtain, and not made with the care that the recent ones are. Consequently, the greater number of cases which nowadays appear are due to more research work on rabies.

3. The fatality among Pasteur-treated patients is less than 1 per cent.

4. From 15 to 20 per cent. is considered a moderate estimate of the death-rate for all persons bitten by rabid animals.

### ARTICLES ON PTOMAINS

*To the Editor:*—Please give references to the literature on the subject of ptomains.

Edward P. Fick, M.D., Seattle, Wash.

Answer.—The following is a list of articles on ptomains which have been listed in our indexes during the past ten years:

Bertrand, D. M. and Berthelot, A.: Ptomain-Producing Bacteria in Human Intestinal Flora, *Lancet*, London, Feb. 22, 1913.
Salmon, J. M.: Ptomain Poisoning, *Kentucky Med. Jour.*, June 1, 1912.
Rodman, H. D.: Ptomain Poisoning, *Kentucky Med. Jour.*, May 1, 1911.
Peck, G. W.: Ptomain Poisoning: Eleven Fatal Cases, *South. California Pract.*, March, 1910.
Bryson, M.: Ptomain Poisoning from Mutton, with Marked Bradycardia, *Brit. Med. Jour.*, Dec. 14, 1907.
Black, S. P.: Pathology of Ptomain Poisoning, *South. California Pract.*, July, 1907.
Sheppard, C.: Three Cases of Fatal Ptomain Poisoning, *South. California Pract.*, July, 1907.
Hungerford, W.: Ptomain Poisoning or Typhoid: Report of Two Cases, *South. California Pract.*, October, 1907.
Anderson, Martha: Ptomain Poisoning, a Case, *Woman's Med. Jour.*, July, 1904.
Barton, P. H.: Ptomain Poisoning, *Cleveland Med. and Surg. Reporter*, October, 1906.

When the ptomains were first discovered it was naturally supposed that all food-poisoning was due to alkaloidal poisons; but subsequent investigation has shown that the alkaloids of putrefaction (ptomains) are comparatively seldom the cause of the poisoning observed. More frequently the condition is an infection, often with the paratyphoid bacillus.

### CAUSE OF DISCHARGE FROM THE MOUTH

*To the Editor:*—A man, aged 60, during heavy sleep at night has coming from his mouth a dram or so of very offensive-smelling, bloody discharge. This occurs at irregular intervals, possibly once a week. The breath is without odor, and there is no mouth or throat condition which accounts for the discharge. Please give the origin and cause of this discharge.

James L. Tracy, M.D., Toledo, Ohio.

Answer.—It is, of course, impossible to form a valid opinion as to the cause of such a discharge, except by very careful local examination. We would suggest that the discharge might be from the sphenoidal sinus. A careful examination with the rhinoscope ought to furnish information with regard to this point.

### WORKS ON HELMINTHOLOGY

*To the Editor:—Referring* to the inquiry of W. H. H. of DeRidder, La., for information relative to books on intestinal parasites, permit me to add the following to the titles given in The Journal, Oct. 25, 1913, p. 1557:

Doflein, F.: *Lehrbuch der Protozoenkunde*, Ed. 3, Jena, Gustav Fischer, 1911.
Mense, Carl: Handbuch der Tropenkrankheiten, Ed. 2, Leipsic, Johann Ambrosius Barth, 1913.

*The latter work* is published in three volumes; of the second edition only one volume has as yet been issued. Dr. A. Looss, concerning whom W. H. H. inquires, contributes a large portion of the helminthology to this and the first editions.

L. P. H. Bahrenburg, M.D., Galveston, Tex.,
Surgeon, U.S.P.H.S.

*To the Editor:*—My attention is called to your note referring to works on intestinal parasites (The Journal, Oct. 25, 1913, p. 1557). In the interests of the general worker, this list should be revised. *Only the first reference* is actually of any value to such a man. *The second* reference is to a laboratory manual for use in college courses, the third to a single *one* of the numerous papers dealing with a particular kind of parasite. The subsequent papers by Dr. Stiles are *of great* value to the research worker but of less value to others. Probably to most of those who write you for information such papers would be unintelligible.

The work by Looss to which reference is made is one of the chapters, namely, *that on* intestinal parasites and intestinal diseases, in Mense's "Handbuch der Tropenkrankheiten." The best works for use by American worke[illegible] sler's "Modern Medicine," Volume I, and "A [illegible]" edited by Allbutt and Rolleston, Volume II, [illegible] individual chapters deal with animal parasites in a complete and authoritative fashion.

Henry B. Ward, M.D., Urbana, Ill.

## Miscellany

### Activities of the American Medical Association

The laudable work of acquainting pharmacists with the work of the American Medical Association, especially in its relations to pharmacology and the traffic in proprietary medicines, has been well performed by L. E. Warren, Ph.C., B.S., in an article in the *Journal of the American Pharmaceutical Association*, March 1913. The author describes the organization of the Association and the work of the various councils. He dwells on the work of the Council on Pharmacy and Chemistry of which he says:

"*The Council on Pharmacy and Chemistry.*—For many years previous to the establishment of the Council on Pharmacy and Chemistry the medical profession had been at the mercy of dishonest manufacturers of proprietary medicines. The simplest drug mixtures were exploited as "new synthetics" under the most outrageously extravagant claims for therapeutic worth. Numerous cod-liver oil preparations that contained little or no cod-liver oil were foisted on the helpless doctor. Consumption remedies that were practically nothing but canesugar were sold at high prices. Detail men from the manufacturing houses, having no knowledge of medicine or pharmacy, brazenly assumed to teach physicians how to treat disease. Every imaginable kind of fanciful fraud was advertised to the profession. Year after year committees were appointed by the American Medical Association in an endeavor to remedy these evil conditions. Resolution after resolution condemning the practice was passed, but the manufacturers went serenely on humbugging the doctor and his patients. One of the methods that was hit on by the Association for compelling the manufacturers to tell the truth about their products was to compel the divulgence of the formula for every preparation that was to be advertised in the Association's Journal. The medical profession then thought that the perplexing problem had been settled. But immediately some of the most wonderful "formulas" appeared in the advertisements in medical journals! Many were chemical impossibilities. Doubtless to physicians they were sometimes imposing. To chemists they were often extremely absurd. A thorough trial of the new system demonstrated that conditions were but little better than before. After much deliberation the American Medical Association established the Council on Pharmacy and Chemistry, which began the difficult task of "separating the sheep from the goats" in proprietary medicines.

The work of the Council on Pharmacy and Chemistry has a more direct bearing on pharmacy and exerts a greater influence on pharmacists than the activities of any or all of the other councils of the American Medical Association."

The work of investigating proprietary medicines, especially those with doubtful or fraudulent claims as to origin or composition first claimed the attention of the council, largely to the neglect of therapeutic problems. The investigations made of worthless, non-proprietary drugs, of various medicinal foods, of serums and vaccines are mentioned. The more recent studies on therapeutic problems are then taken up:

"*Having* practically completed the examination of proprietary medicines the council has turned a portion of its attention to problems of therapeutic research. One of these which is not yet completed is a study of the relative toxicity of synthetic salicylic acid and its compounds as compared with that of the acid occurring in plants. For many years certain manufacturers and physicians have maintained that synthetic salicylic acid owing to its impurities is more irritating—more poisonous—and consequently less efficient therapeutically, than that made from natural oil of birch or wintergreen. Others believe that there is no difference. The problem is being attacked by the Council's research committee from its chemical, clinical and pharmacologic sides. Its solution will be of great interest to science and may be of great economic benefit

> to pharmacists since the acid from natural sources costs from ten to fifteen times as much as the other kind. After exhaustive studies on cats, mice and rabbits the pharmacologic investigators have reported that they could find no difference in toxicity for these animals between the two classes of preparations. The reports of the chemical examination and of the clinical studies, each of which has been carefully carried out, have not as yet been published, but it appears probable that the findings will show that the synthetic salicylates are not less pure than the natural, that the one is not more toxic than the other and that there is no difference in the therapeutic value of the two.
>
> The question of intestinal antisepsis has been studied by the Council's research committee. For a long time it had been supposed by many physicians that certain drugs when taken internally would prevent or greatly retard the bacterial decomposition of food in the large intestine with the resultant formation of indol compounds and related poisons. Others have doubted the efficiency of the reputed intestinal antiseptics. At the Council's suggestion a well-known bacteriologist undertook to determine whether there really are any intestinal antiseptics. His results, while not absolutely conclusive, show that intestinal antiseptics cannot play as important a rôle in therapeutics as had previously been supposed, and that they are probably of little value."

The necessity of determining the composition of proprietaries and of detecting false claims led to the establishment of one of the most important departments of the association's work, the chemical laboratory. The author describes as follows the reference library connected with the laboratory:

> "A most comprehensive and complete reference library containing the latest and best books on chemistry, pharmacy and the allied sciences, has been collected by the laboratory and every important pharmaceutical and chemical journal published in any language is to be found there. The average reader may not appreciate all that this means. It means that the latest and most reliable data concerning new drugs—proprietary or otherwise—from all parts of the world are now at the disposal of the medical profession of America. The larger manufacturing houses have long realized the value of such data for purely commercial purposes, and they have been careful to keep in touch with what was going on outside this country, and were ever on the watch for anything new which might develop and which could be used by them. Physicians, however, have been among the last to learn the facts regarding new remedies; the information which manufacturers collected so zealously for themselves was not allowed to trickle out among the medical profession until it had been colored, flavored and sophisticated, often out of all likeness with the original, but always into apparent praise of the preparations marketed under trade-marked names.
>
> "In connection with this work there is being made an ever-increasing collection of information on practically every pharmaceutical or medical humbug that has come before the public in recent years. This information is collected from the federal notices of judgment under the Food and Drugs Act sent out by the government, from reports of state and municipal food and drug laboratories and from foreign journals. It can be said without fear of contradiction that there are few reports of the analyses of medicines, if at all valuable, whether made here or abroad that escape the watchful eyes of the laboratory staff. Inquiries for information about medical frauds and fakes are constantly being received. A few of these are answered through THE JOURNAL of the American Medical Association, in its department of Queries and Minor Notes, but the limitations of space make it necessary to answer the great majority by correspondence. This work is done by the laboratory staff or by an official of the Propaganda Department. As a correlated branch of the laboratory's work, a "testimonial file" has been compiled in the Propaganda Department which contains the names of several thousand physicians who have written testimonials for various proprietary preparations. As an illustration of the use that is made of this file I will quote from an article in THE JOURNAL of the American Medical Association of recent date:
>
> " 'Of 104 physicians who had written testimonials for Duffy's Malt Whiskey, five are members of the American Medical Association, and eighteen have written testimonials for other nostrums. From our files it appears that some of the 104 testimonial-givers are either advertising quacks or are connected with fraudulent medical concerns. It is not difficult to estimate the scientific value of testimonials that come from such sources.'
>
> "Doubtless the greatest value of the laboratory work has come through the fearless publicity which THE JOURNAL of the American Medical Association has given to the laboratory's exposures of the shortcomings of pharmaceutical manufacturers. No firm has been so large or so powerful as to escape criticism of its products or its methods, if criticism were needed; and no firm has been so small or so insignificant as not to receive credit for worthy preparations, if credit were due."

Warren contrasts this fearlessness with the subservient caution exercised by certain state laboratories in removing from their exhibits of adulterated goods the names of manufacturers. The abuses of nomenclature and of the use of copyrighted names are discussed. Warren continues:

> "Work of this kind by the Council on Pharmacy and Chemistry is of very great value to the individual pharmacist. It seems to me that it is the duty of pharmaceutical journals to bring these and similar facts to the attention of the pharmacists. If the journals themselves are not in position to make the investigations they can at least abstract the investigations made by the Council on Pharmacy and Chemistry."

Finally he illustrates the work of the Association by a summary of the results of investigation of certain frauds, such as Waterbury's Cod-Liver Oil Compound, prescription fakes, fake "gall-stones," En-Ar-Co Oil, Jaroma, Plantoxine, Thacher's Worm Syrup, Chichester's Diamond Brand Pills, sulphur dioxid cure-alls, Midol and Nurito, Murine, Sanatogen, vile-smelling cure-alls, such as Sulphurro, the "gas-pipe" cures and Lung-Germine.

The work of the American Medical Association in endeavoring to aid the public to obtain a broader conception of public health matters is praised and its exhibition at the International Congress of Hygiene and Demography is described. The author concludes:

> "The American Medical Association believes that the public, the pharmaceutical profession and the medical profession must all work together to abolish the public drinking-cup, to exterminate flies and mosquitoes, to eliminate the adulteration of foods, to prevent the pollution of water-supplies, to secure adequate disposal of garbage, to insure the proper cleaning of the streets in cities, and, in short, to perform any other tasks which tend to raise the standard of health and lower the death-rate of our citizens."

---

## Shorter Papers

Writers of scientific papers on medical and surgical subjects will conserve their own interests as well as the convenience of those who listen to their reading, and those who will afterward enjoy the privilege of publishing them, by making them as short as is consistent with clearness of expression and the completion of the subject. As a rule there are few reasons for any paper to contain more than three thousand words, occupying about four pages of this journal. Outside of official documents and reports which cannot properly be abbreviated, only the description of a long series of important cases, similar in kind, but with noteworthy variations, should warrant a paper longer than that described, and even under such circumstances three thousand words should generally tell the story. Many of the very long papers read to tired audiences at every meeting of medical men are mere aggregations of quotations, recounting what this or that eminent man has written on the subject, giving copious references to book and page and stringing the whole together on a slender thread of personal observation. Their authors would do well to consider that in all probability most of the members of their audiences are as widely read as themselves, and sufficiently familiar with the opinions of the eminent men referred to to understand the subject without so many quotations and references. This is said in all kindness and not in a spirit of criticism. The spirit of the age demands concentration, and the concise, lucid and logical paper that tells its story in as few words as are compatible with complete expression and then stops will receive the most respectful attention and have the most satisfactory effect. By all means let us have short papers.—*Southern Med. Jour.*

## MEDICAL DEFENSE IN CANADA

The Canadian Medical Protective Association is an organization of physicians in Canada for the purpose of mutual assistance and protection against malpractice suits. It has been in existence for twenty-four years, but has only recently been incorporated by an act of the Dominion parliament. The articles of incorporation give the objects of the association as follows:

1. To support, maintain and protect the honor, character and interests of its members.
2. To encourage honorable practice of the medical profession.
3. To give advice and assistance to, and defend and assist in, the defense of members of the association in cases in which proceedings of any kind are unjustly brought or threatened against them.
4. To promote and support all measures likely to improve the practice of medicine.

The objects of this organization are considerably broader than those of similar societies, as assistance is not limited to malpractice suits, but to any unjust proceedings brought against members. The constitution, in addition to enumerating the four objects given in the act of incorporation, provides that the association shall assist in defending civil actions for damages for alleged malpractice "where such actions appear to the executive committee and to the general counsel of the association to be unjust, harassing or frivolous, or where it appears otherwise to be reasonable to afford the member whose conduct is impeached an opportunity of defending himself before a court of law."

Any member of the medical profession in good standing in Canada is eligible to membership. Applicants must be nominated and seconded by two members and must present the qualifications required for membership in the Canadian Medical Association. A local advisory committee of one or more members in each province may pass on the application for membership. The annual dues are $3. Members are liable for dues until their resignations are accepted, and provision is made for the collection of dues by draft or other agencies. The president's report for 1913 shows an increase in membership of sixty during the past year. The solicitor's report shows that in Canada, as in this country, most of the actions brought or threatened were dropped before they reached a hearing. The treasurer's report shows a membership of 812. The annual dues of $3 per member give the organization an average annual income of $2,500.

The general plan of this organization is, in the main, similar to that adopted by some of our state societies in providing for medical defense. The annual dues are larger, as most of our state associations have found it possible to provide entirely adequate defense for $1.50 per member per year. The fact that such an association with a membership of approximately eight hundred has been able to carry on this work on a $3 basis for twenty-four years is ample proof of the soundness of the plan and of the possibility of even the smaller state associations being able to furnish such protection to their members.

**Diagnosis of Intussusception in Children.**—Turning now to the symptoms of this disease (acute intussusception), there are three which are of great importance in the diagnosis of the condition in children. They are the sudden onset of screaming in a previously healthy infant, followed by vomiting and the passage of stools containing blood and often consisting of blood and mucus only, without any fecal material, the symptoms occurring in this order. In a child they are pathognomonic.—James Sherren, in (London) *Clinical Journal.*

# Medical Education and State Boards of Registration

## COMING EXAMINATIONS

Delaware: *State Society and Homeopathic, Dover and Wilmington, Dec. 9-11.* Secretary of the Medical Council, Dr. Henry W. Briggs, 1026 Jackson St., Wilmington.

Kentucky: Armory, Louisville, Dec. 11-13. Sec., Dr. J. N. McCormack, Bowling Green.

Maryland: Regular, 1211 Cathedral St., Baltimore, Dec. 9. Sec., Dr. J. McP. Scott, Hagerstown.

Ohio: Columbus, *Dec. 9-11. Sec., Dr. Geo. H.* Matson, State House.

Pennsylvania: *Philadelphia,* Dec. 2-4. Sec., Mr. Nathan C. Schaeffer, Harrisburg.

Virginia: Richmond, Dec. 16-19. Sec., Dr. Herbert Old, Norfolk.

### First Examination by the Canadian Medical Council

The first examination conducted under the provisions of the new Canada Medical Practice Act was held at Ottawa, Canada, in October. The results sent us by Dr. R. W. Powell, the Registrar of the Medical Council of Canada, are as follows: Of the 71 candidates examined, 44 passed, 8 were referred back to the council, having failed in not more than two subjects, and 19 (27 per cent.) were rejected. It is understood that certificates granted by the Medical Council of Canada permit the candidates to practice in any province of their choice without further examination.

### Missouri September Report

Dr. J. A. B. Adcock, secretary of the Missouri State Board of Health, reports the oral and written examination held at Kansas City, Sept. 2-4, 1913. The number of subjects examined in was 14; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 38, of whom 27 passed and 11 failed. Seven candidates were licensed through reciprocity. The following colleges were represented:

PASSED

# *Book Notices*

The Examination of Waters and Water-Supplies. By John C. Thresh, D.Sc., M.D., D.P.H. Second Edition. Cloth. Price, $5 net. Pp. 644, with 53 illustrations. Philadelphia: P. Blakiston's Son & Co., 1913.

The first edition of this book was published in 1904 and is well known to water analysts. Apart from the introduction of new details and illustrations and some important additions to the discussion of water standards, there are few noteworthy changes. So far as a bacterial standard is concerned the author seems inclined to adopt Houston's well-known views, according to which a water is to be regarded as safe when it never contains *Bacillus coli* in 100 c.c. samples; reasonably safe when it contains *B. coli* in less than half the number of 100 c.c. samples examined; suspicious (in Houston's words "to be viewed with some degree of preliminary disfavor") when it contains *B. coli* in a majority of 100 c.c. samples. These standards call for a higher degree of purity than that possessed by those public water-supplies in this country which are usually regarded as of excellent quality.

Some remarkable lapses of judgment are apparent: as when the author remarks (page 64) ". . . it is doubtful whether this organism [*B. typhosus*] alone can induce the disease. I have imbibed millions of them and so has Dr. Houston, yet neither is one penny the worse. Every known fact with reference to epidemics of this fever indicates that the typhoid bacillus alone is not the cause of the disease, and it has long been suspected that some other organism, either by itself or in conjunction with the typhoid bacillus, was the cause." This with reference to a "discovery" by Loris-Melikoff of an anaerobic bacillus in typhoid stools. A curious light is thrown on some English epidemiology by the following passage (pages 65-66): "There is no question that many outbreaks are referred to drinking-water which are due to other causes. It is only necessary for an outbreak to occur for the water to become suspected, and failure to trace the infection to any other source leads to the water being condemned, especially if there is discovered any possible, however improbable, source of contamination. There is scarcely a water-supply in the country which does not stand to be condemned at some time on such evidence. Naturally an investigator does not like to acknowledge himself baffled in his endeavor to discover the cause of an outbreak of typhoid fever, and, rather than acknowledge defeat, the water-supply is condemned. This can be safely done because it is practically impossible for the water authority to prove the negative."

A Manual of Venereal Diseases. Introduction by Sir Alfred Keogh, K.C.B.; History, Statistics, Invaliding, Brevet-Colonel C. H. Mellville, R.A.M.A.; Clinical Pathology and Bacteriology, Brevet-Colonel Sir William Leishman, K.H.P., F.R.S., R.A.M.C.; Clinical Course and Treatment, Major C. E. Pollock, R.A.M.C. Second Edition. Cloth. Price, $3.75. Pp. 318, with 30 illustrations. New York: Oxford University Press, 1913.

This volume is the result of an attempt to make a report of a committee of the medical advisory board of the British Army more valuable to the ordinary military surgeon. After an introduction by Sir Alfred Keogh, the main part of the work, in which individual authorship is not distinguished, constitutes an ordinary treatise on syphilis with a shorter account of gonorrhea and soft chancre. The first chapter on history is mainly concerned with methods of prevention. The failure of former British and present Continental efforts to suppress venereal diseases by regulating prostitution is admitted, and a plan outlined for troops which includes as its first measure an appeal to the high ideal of a chaste life. When such appeal and proper educational measures fail a moderate form of punishment is advocated. The great value of physical exercise is recognized. The purely medical chapters have been revised so as to incorporate the recent advances in the diagnosis of syphilis and the most modern treatment of venereal diseases. The book is thus not merely a book for the military surgeon, but also cannot fail to be useful to the physician in private practice.

Tuberculin Treatment. By Clive Riviere, M.D., F.R.C.P., Physician East London Hospital for Children, and Egbert Morland, M.B., B.Sc., M.D., Visiting Physician to the English Sanatorium. Second Edition. Cloth. Price, $2. Pp. 247. New York: Oxford University Press, 1913.

This book aims to give the needed advice to the practitioner who wishes to apply this method of treatment. The essential unity of the various forms of tuberculin is insisted on. Two divisions of tuberculin treatment are made, first, tuberculin immunization with tolerance, which they recommend for pulmonary tuberculosis; and, secondly, tuberculous immunization without tolerance—the method employed by Wright in the treatment of local tuberculosis. In this method small doses are employed at considerable intervals without provoking distinct reactions. This form is regarded as especially suitable to children. It would seem that the recognition of the suitability of the two methods to distinct forms of disease is a great gain in clearness as to the indications for the use of this powerful agent. The directions for technic are full and clear. Dosage is reckoned in cubic millimeters instead of fractions of the cubic centimeter.

Backward and Feeble-Minded Children. Clinical Studies in the Psychology of Defectives, with a Syllabus for the Clinical Examination and Testing of Children. By Edmund Burke Huey, A.M., Ph.D., Lecturer on Mental Development in the Johns Hopkins University. Price, $1.40. Pp. 221, with illustrations. Baltimore: Warwick & York, 1912.

The importance of the problem of the feeble-minded has attracted a great deal of attention in recent years, and has resulted in an ever-increasing stream of literature. In this book attention is called to the fact that the vast majority of the feeble-minded are outside of institutions and for some period of their early life are pupils in our public schools. Of those admitted during one year to the Lincoln (Ill.) Institution for the Delinquent, at which the author made his observation on the feeble-minded, 43 per cent. had attended the public schools for one year or more. He says that, except in the case of infrequent offenders and persons whose mental disturbance is due to specific kinds of poisoning, even in their school period these children usually show exceptional conduct and can be picked out by any one trained in clinical observation. He believes that here is an opportunity for studying in advance the main sources of social danger, and of individual misfit and shipwreck. Teachers have opportunity for making observations and rendering exceptional service in this regard. The immediate need is for special classes for children likely to become delinquents. The author considers the subject under the heads of classification and terminology and clinical study of border cases. He gives data of suggested groups and lines of transition from feeble-mindedness to non-feeble-mindedness, and discusses the mental functions to be tested and observed. Many illustrative cases are given, with photographs.

Anatomy, Descriptive and Applied. By Henry Gray, F.R.S., Lecturer on Anatomy at St. George's Hospital Medical School. A New American Edition with the Ordinary Terminology followed by the Baske Anatomical Nomenclature in Latin. Revised by Edward Anthony Spitzka, M.D., Director of the Daniel Baugh Institute of Anatomy. Cloth. Price, $6 net. Pp. 1502, with 1225 illustrations. Philadelphia: Lea & Febiger, 1912.

The new American edition of Gray's "Anatomy" succeeds at the end of three years the eighteenth edition. It differs very little from its predecessor, which is only to be expected, since three years bring little change in the science. Fifty years' continuous practice has enabled the editors of this text-book to approach very near to perfection in the manner of presenting the subject.

## Care Required in Application of Hot-Water Bottles

*(Williams vs. Pomona Valley Hospital Association (Cal.), 131 Pac. R. 888)*

The District Court of Appeals, Second District, California, reverses a judgment for the defendant and an order denying a new trial in this case, which was brought to recover on account of personal injuries occasioned by reason of alleged negligence on the defendant's part. The complaint alleged the plaintiff's entrance as a patient into the defendant's hospital, and that, while in the hospital and unconscious, a servant of the defendant placed hot-water bags on or about the plaintiff's feet in such a careless and negligent manner that the plaintiff's feet were badly burned and scalded, from which he suffered damages. The court says that certain instructions given to the jury could have had no other effect than to have told them that when the nurse applied the hot-water bottle to the feet of the plaintiff, exercising ordinary care in the manner in which the same was placed, she was absolved from all further care or attention in relation to the patient as regards the effect produced by the application of the hot-water bottle. The court is of opinion that too restricted a construction was given to the averments of the complaint.

The word "manner," in the connection under consideration, means the way of doing anything. The use of the term "manner" in the complaint should be taken to comprehend the way the act was performed, having in view the condition of the patient and the character of the remedies applied. To place a hot-water bottle of such high temperature on the feet of an unconscious man as would burn or scald the feet cannot be said to be a proper way of doing such a thing; and a pleading which refers to the manner as having produced the injury should be given such a liberal construction as would work substantial justice between the parties. To give it the construction adopted, that the subsequent effect of the application in producing burns and scalds was not to be considered, eliminated from the consideration of the jury one of the vital and principal questions presented.

The duty of a nurse, and assuming that a nurse must only exercise the ordinary care which a trained and skilled nurse would be required to use, is a continuous duty. Dealing, as she was, with an unconscious patient, unable to care for himself, it was her duty to observe the effect on the patient of the application of the remedy as much as it was to test its temperature in the first instance. The powers of resistance, the condition of the patient, must of necessity have much to do with the application of remedies, either by a physician or a nurse, and this duty could be observed only by constant and unremitting care and attention, which is just as obligatory on the nurse as is the duty of applying the remedy directed by the physician in charge.

## Supremacy of Powers of Boards of Health—Power to Close All Dairies in City

*(Alston vs. Ball (S. C.), 77 S. E. R. 727)*

The Supreme Court of South Carolina says that the defendants, comprising the board of health of the city of Charleston, passed a resolution requiring all dairies in the city to be closed on or before July 1, 1912. The plaintiffs, who were conducting a dairy within the city, brought this action to enjoin the board from enforcing the resolution. A judgment in favor of the defendants is affirmed.

As the city council undertook, by resolution, to nullify the action of the board of health, the first question to be decided was, Which of these bodies had superior authority in the premises? Under the constitution and statutes, boards of health derive their powers directly from the legislature, and not from the municipalities. Therefore the council was without power to nullify the action of the board of health.

Sections 1451 and 1463 of the Civil Code of 1912 confer ample authority on the boards of health to make and enforce all needful rules and regulations to prevent the introduction and spread of infections or contagious diseases, and generally to make all such regulations as they shall deem necessary for the preservation of the public health, and to define, declare and abate nuisances injurious to the public health. Therefore the board had authority to pass the resolution in question.

As the powers of boards of health are conferred on them by the legislature, it follows that, as long as their actions are not arbitrarily or capriciously taken, and are confined within the limits of powers constitutionally conferred on them, they are subject to no control except that of the legislature; and the court will review their actions only so far as may be necessary to see that they bear a just and reasonable relation to the object sought to be attained, and do not invade personal or property rights vouchsafed to the citizen by the constitution. Within the limits of their power, they are the exclusive judges of the propriety and wisdom of their actions, and so long as they act strictly within those limits, and not arbitrarily or capriciously, they are not subject to the control of the court. In other words, the court cannot set its judgment against theirs, for that would be to usurp their powers. Under the showing made, it could not have been said that the action of the board in this case was arbitrary or capricious, or that it had no substantial or reasonable relation to the purpose for which it was intended, namely, the protection and preservation of the public health. On the contrary, the overwhelming weight of the evidence was that it was not only desirable, but necessary to that purpose.

## Power of a Municipality to Deal with Earth-Closets

*(Malone vs. City of Quincy (Fla.), 62 So. R. 922)*

The Supreme Court of Florida holds that if earth-closets in a city for any reason become a nuisance or otherwise unlawful, the municipality may by reasonable regulations abate them, or otherwise deal with them as the charter powers may authorize. But the power of a municipality to prohibit the use of earth-closets within its limits cannot be implied merely from authority expressly given to regulate their use; and power to prohibit the use of earth-closets in a city is not conferred by general power given to conserve the public health and general welfare, when the authority to regulate the use of earth-closets is expressly conferred in definite terms, limited in their scope and purpose. When the use of earth-closets is contemplated by a municipal charter, and express limited authority is given to regulate the use of them, their proper use as such is not unlawful, and cannot be prohibited by the municipality, in the absence of express authority to do so, or unless such closets become a nuisance, or their use is otherwise unlawful and within the power of the city to abate or prohibit.

The express authority given the city "to regulate the construction, location and arrangement of earth-closets" in the connection used in the charter act of Quincy has reference to the location of such closets as they are used on property in the city, and does not authorize a prohibition of the proper use of earth-closets in any part of the city. Nor does the express authority to issue bonds for construction and maintaining waterworks and a "system of sewerage" give the city power to prohibit the use of earth-closets. An ordinance forbidding the use of earth-closets in designated portions of the city of Quincy, without reference to whether such closets are a nuisance, is not authorized by the charter act, and a judgment of the municipal court, imposing a penalty for a violation of such ordinance, is invalid, and may be quashed.

### Validity of Tenement-House Act Requiring Certificates of Health Department

(*Ex parte Stoltenberg* (*Cal.*), *132 Pac. R. 841*)

The District Court of Appeals, Second District, California, holds constitutional, as a reasonable exercise of the police power, the tenement-house act of that state, which provides that no building hereafter constructed as or altered into a tenement-house shall be occupied in whole or in part for human habitation until the issuance of a certificate by the health department or other department by municipal ordinance designated for that purpose, that said building conforms in all respects to the requirements of this act relative to the light and ventilation and sanitation of tenement-houses, etc. The court says that, generally speaking, all of the provisions, conditions and restrictions imposed by the act relate to matters affecting public health, safety and the public welfare. The police power deriving its existence from the rule that the safety of the public is the supreme law, justifies legislation on matters pertaining to the public welfare, the public health or the public morals. Legitimate business, as well as those things which are nuisances in and of themselves, is subject to control if control is necessary for the preservation of the public health and welfare. Nor does the fact that the section above referred to gives to certain officials authority to determine questions relative to compliance with the law render the act invalid. It will not be presumed that authority will be exercised wantonly or for purposes of profit or oppression.

### Appeal the Only Remedy for Unfavorable Action on Bills

(*Hoyt vs. Hughes County* (*S. D.*), *142 N. W. R. 471*)

The Supreme Court of South Dakota, in reversing a judgment rendered in favor of the plaintiff, says that he had presented at a meeting of the board of county commissioners a bill for $514.60, most of which was for personal services claimed to have been performed as superintendent of the county board of health. A small portion of the bill was for mileage and reports made by the plaintiff. The board of county commissioners allowed $32.90 of this bill, and rejected the balance of $479.70. No appeal was taken by the plaintiff from the action and decision of the commissioners in rejecting and disallowing the $479.70 of the bill, but he some time thereafter brought this action against the county to recover that balance. The county urged that the plaintiff could not maintain the action to recover the balance of account—that the plaintiff's only remedy under the circumstances was by appeal from the action and decision of the county commissioners, and not by direct action. The court is of the opinion that the defendant's contention was well grounded. It is not the method or manner or result of the manner in which such a board acts that precludes the maintenance of an original action, but it is the fact that the board has acted in a matter within its exclusive discretionary power, and having so acted, no matter how erroneously, such action can be reviewed only on appeal.

Some contention was made that the power granted by Chapter 76 of the laws of South Dakota of 1905 to the county commissioners, providing that for certain services the county superintendent of the board of public health shall receive such sums as the county commissioners may allow, is a grant of purely legislative power, the exercise of which is not subject to appeal at all. The court, however, is clearly of the opinion that the power granted to the county commissioners by this section of the statute is not a grant of legislative power, but is a grant of discretionary power to be exercised in a quasi or sort of judicial manner, and is subject to appeal under Section 850 of the political code. But, no matter whether the power granted is quasi-judicial or legislative, a direct action cannot be maintained on such a claim.

Chapter 76 of the laws of 1905 regulates the compensation of the superintendent of the county board of health. The entire amount of the items rejected was included within the provision of the statute for "such other sums as the board of county commissioners may allow," and clearly within the discretionary powers of the county commissioners. The commissioners had the right to investigate the facts in connection with such allowance, and base and form their judgment on the evidence before them. If they erred in such judgment as to such allowance, the plaintiff's only remedy was an appeal for the purpose of reviewing and correcting such action. Courts cannot control such acts of such boards by compelling them to act in any particular manner. Courts can compel them to act, but, having acted, such acts become final unless reversed on appeal, when an appeal is provided for by law.

### Employment of Physicians by Overseers of Poor

(*Meyers vs. Furnas County* (*Neb.*), *140 N. W. R. 633*)

The Supreme Court of Nebraska holds that, under the provisions of Section 14 of Chapter 67 of the compiled Statutes of 1911, if any person, not coming within the definition of a pauper, shall fall sick within any county of the state, not having money or property to pay his or her board, nursing and medical aid, it is the duty of the overseers of the poor of the precinct in which the person shall be to furnish such assistance as they shall deem necessary. This gives the overseer full authority to provide the necessary medical aid to the sick person. When a physician is employed by an overseer of the poor to give medical aid to a destitute person who has fallen sick, and the service required is performed, the fact that the overseer has not made a written report of his doings thereon to the county board cannot defeat the liability of the county for the service rendered under such employment. The averment in a petition that a person had fallen sick under such circumstances as to show her destitution and inability to provide for herself, or be provided for by others, is a sufficient allegation of the dependence on the county, when assailed by a demurrer.

### Amendment of Petition in Malpractice Case—When Verdicts Will Not Be Disturbed

(*Blakeslee vs. Van der Slice et al.* (*Neb.*), *142 N. W. R. 799*)

The Supreme Court of Nebraska affirms a judgment for the plaintiff for damages alleged to have been sustained by a failure of the defendants to properly reduce a fracture of her arm, commonly called Colles' fracture. The court says that it does not think it error that the plaintiff was allowed to amend her petition at the close of the evidence, when she asked leave to amend it by changing the word "ulna" to the word "radius" in furtherance of justice and to conform to the facts proved. To the court it seems clear that the amendment asked for could not and did not in any way mislead the defendants. The case has been tried on its merits, and whatever discrepancy appeared in the petition was properly cured by the amendment, and the defendants were not thereby misled to their prejudice. It is usually a matter within the discretion of the district court to allow or refuse to allow a pleading to be amended to conform to the evidence, and, in order to predicate error in allowing the amendment, it must be shown that the trial court has abused its discretion.

Nor could it be said that there was reversible error in permitting counsel to propound questions to witnesses pertaining to a book or treatise on the "Treatment of Fractures," so long as there was nothing in the record showing, or tending to show, that this work or any part of it was introduced in evidence, and whatever reference there was made to it was confined to the fact that there was such a work, and was without prejudice.

It was claimed by the defendants that the plaintiff violated their instructions not to use the broken arm or hand, but the evidence on that question was conflicting, and the verdict of the jury should not be disturbed. When the issues in such an action are all submitted to a jury, under proper instructions, the verdict will not be set aside unless it is shown to be clearly wrong.

Western Surgical Association, St. Louis, Dec. 19-20.

## CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA

*Fourth Annual Session, held in Chicago, Nov. 10-15, 1913*

The President, Dr. George Emerson Brewer, New York, in the Chair

### Preliminary Report of a Simple and Rapid Method of Pyloric Closure in Gastro-Enterostomy

Dr. **George Emerson Brewer**, New York: The only safe method is the unilateral pyloric closure suggested in 1895 by von Eiselsberg. My method consists in constriction of the pylorus by an aluminum band, which is easily passed round the tube at this point, and quickly rolled with the fingers into an unyielding ring with sufficient compression to obliterate the lumen of the tube, but not to compromise the vitality of the compressed tissues. From a study of experiments on dogs, it is evident that this method of closure produces a complete occlusion of the pylorus, as proved by the facts that water will not pass the constricted point when the stomach is distended, and that sections through the pylorus and aluminum ring show by gross and microscopic examination not only that the pylorus is closed, but also that the vitality of the tissues is not impaired. A second series of experiments shows that the same method can be applied to the pyloric antrum, and also that the pylorus which has been closed for some months can have its function again restored by a second laparotomy and removal of the aluminum band.

### Report of a Series of Gasserian Ganglion Operations

Dr. **Harvey Cushing**, Boston: I have done 156 operations on the gasserian ganglion with two fatalities, which occurred in the earlier cases. In 100 consecutive cases there were operations on 46 males and 54 females. The neuralgia affected the right side in 62 cases, the left side in 36, and both sides in 2. It has long been the impression that these neuralgias occur much more commonly on the right side, but in the last fifty cases there has been an unusual number of left-sided neuralgias, which has brought the percentage up to 36, whereas previously the ratio between neuralgias of the right and left sides was about 3:1. The average age at operation was 55 years, the youngest patient being 26, and the oldest 86. The average age at onset was 45, the youngest 18 and the oldest 74.

### Gastric Hemorrhage

Dr. **John B. Deaver**, Philadelphia: Gastric hemorrhage, as a rule, is followed by hematemesis, and results from a number of disturbing factors in the mechanism of the upper abdominal circulation. In the minority of cases the blood is not at once ejected, but is passed subsequently by the bowel in the form of tarry stools. Cases of gastric hemorrhage fall into two groups, the surgical and the non-surgical. It is as great a mistake to operate in non-surgical cases as it is to withhold operation in surgical bleeding. Profuse and even fatal hematemesis without demonstrable ulceration of the stomach has been observed in a considerable number of cases, both at necropsy and at operation. In 459 of our cases of upper abdominal disease, hematemesis occurred in only 25 per cent. and 20 per cent. of these cases were either simple ulcer or cancer of the stomach. Hemorrhage more or less acute may result from the formation of the typical acute peptic ulcer, the vessels beneath the muscularis mucosa being opened by the ulcerating process. Such hemorrhage is rarely fatal, the vessels opened being small and their walls still soft and normal, permitting retraction and contraction with the formation of an occluding clot as the blood-pressure is reduced by hemorrhage. While it is true that sudden massive hemorrhage does occur in chronic gastric and duodenal ulcer, it is also true that it is not a characteristic of ulcer to bleed profusely. Occult blood or small recurring hemorrhages are far more characteristic of ulcer and it is therefore incumbent on the diagnostician, in the presence of diffuse hematemesis, to adduce considerable evidence in the way of history or examination before concluding that ulcer is present. The hemorrhage due to malignant disease of the stomach, like that of ulcer, is not commonly sudden and profuse. In the early stages it is slight, even occult in the stools. It is more apt to be persistent than the hemorrhage of ulcer and tends to become progressively more marked. The hemorrhage from malignant ulceration is a slow seepage, as a rule, which gives rise to a little systemic effect of bleeding, but reveals itself by the coffee-ground vomitus or melena. Sudden hemorrhage is one of the modes of termination of gastric carcinoma, but in all save the rarest instances such an event is merely the termination of an already established and evident malignant cachexia. Operation may be indicated in gastric carcinoma when hemorrhage chances to be an early symptom and there is still hope of cure; or it may be indicated in advanced or otherwise inoperable cancer when hemorrhage is so profuse and persistent as to shorten even the period of prognosis given to cancer.

### The Operation of Gastrojejunostomy, and the Principles Which Should Determine Its Use

Mr. **Herbert J. Patterson**, F.R.C.S., *London:* There is little doubt that the immediate results of the posterior operation are better than those of the anterior. The patients convalesce more smoothly, and vomiting is less common, while after the anterior operation it may be necessary to wash out the stomach once or twice during the first few days. As to the remote results, I am inclined to think that the advantage rests with the anterior operation. After the posterior operation some patients, although few after remaining well for months or years, begin to suffer discomfort. In some instances this is due to a mechanical defect at the site of the anastomosis, such as a constriction produced by contraction of the mesocolon encircling the anastomosis. I am quite clear that the mesocolon should be sutured to the stomach a little distance away from the suture line, and not to the jejunum or to the suture line as commonly taught. In other cases the defect is due to a kink produced by contraction of a dilated stomach, or to the formation of adhesions, or to rotation of the jejunum on its longitudinal axis during the process of suturing.

It is said that the anterior operation is more often followed by jejunal ulcer, but I do not think there is any positive proof of this. The proportion of unsatisfactory cases is undoubtedly small, not more than 5 per cent. For many years I have been maintaining that the operation of gastrojejunostomy is a physiologic one. Sir Berkely Moynihan, on the other hand, has expressed his belief that the "physiologic explanation of gastrojejunostomy is rot." What is the effect of gastrojejunostomy on the evacuation of the stomach? My experience is that in cases in which there is no organic stenosis of the pylorus, the evacuation of the stomach is slightly accelerated. Usually the stomach is empty in from three to four hours after a meal. Another means of comparing the motility of the stomach before and after operation is afforded by the study of the amounts recovered one hour after a test meal. In 60 per cent. of a series of investigated cases the amount recovered after a test meal was less after operation than before, but the difference is not very great. In sixty-six cases the average amount recovered one hour after a test meal was 190 c.c. before operation, and 180 c.c. after operation. As a rule, when there is organic pyloric stenosis, the motility of the stomach is improved by gastrojejunostomy. I think, therefore, that we may conclude that in those cases in which the gastric motility is impaired markedly by pyloric stenosis or by adhesions, the operation of gastrojejunostomy results usually in a marked improvement in the evacuation of the stomach contents. In those cases, on the other hand, in which before operation the motility is unimpaired, gastrojejunostomy usually slightly hastens, but occasionally retards, the evacuation of the stomach. Inasmuch as this retardation or acceleration falls within physiologic limits, we are justified in saying that in cases in which, before operation, the motility of the stomach is unimpaired, the evacuation of the stomach is unchanged by gastrojejunostomy.

Notwithstanding the absence of Gmelin's reaction in 27 per cent. of my cases, I believe that the presence of bile in the gastric contents is a constant and very important feature after gastrojejunostomy. My reason for this statement is the observation that, after gastrojejunostomy, in 99 per cent. of my cases there is an increase of the mineral chlorids in the gastric juice. This increase is not due to greater activity of the gastric mucosa, because, as a rule, there is (in 75 per cent. of my cases) a diminution of the total chlorids. If, then, this increase in the mineral chlorids be not the result of greater activity, it must be due to chlorids added from without to the gastric contents.

We see, then, that after a gastrojejunostomy there is a constant increase in the mineral chlorids of the gastric juice. This increase must be due to chlorids added to the gastric juice by the entrance of bile and pancreatic juice, because (1) the total chlorids of the gastric contents are diminished; (2) undoing gastrojejunostomy diminishes once more the amount of mineral chlorids; (3) if an entero-anastomosis be performed the increase in the mineral chlorids does not occur, and (4) in cases in which there is a marked excess of mineral chlorids, as a rule the increase in mineral chlorids does not follow operations other than gastrojejunostomy. Doubtless part of this increase is due to neutralization of free hydrochloric acid and consequent formation of sodium chlorid. This does not affect my argument because (1) this neutralization must be caused by the carbonates of the bile and pancreatic juice, and (2) if, before gastrojejunostomy, free hydrochloric acid be absent from the gastric contents, there is still an increase in the mineral chlorids after gastrojejunostomy. To my mind the conclusion is irresistible, that gastrojejunostomy is a physiologic operation.

The four practical lessons to be learned are these: 1. The type of gastrojejunostomy employed is of less importance than the manner in which it is performed. 2. If gastrojejunostomy be a physiologic operation its use for the treatment of gastric hemorrhage is correct and explicable. 3. Occlusion of the pylorus is an unnecessary complication of gastrojejunostomy and is based on erroneous pathology. 4. If gastrojejunostomy be a physiologic operation, then it is as efficient for ulcers of the body of the stomach as for ulcers near the pylorus; in other words, gastrojejunostomy is preferable to excision.

*(To be continued)*

## MEDICAL SOCIETY OF VIRGINIA

*Annual Meeting held at Lynchburg, Oct. 21-24, 1913*

The President, Dr. Southgate Leigh, Norfolk, in the Chair

For a list of the newly elected officers, see The Journal, Nov. 1, 1913, p. 1640.

### Heavy Silk Used to Replace a Destroyed Patella Tendon

Dr. A. R. Shands, Washington, D. C.: The patient was accidentally cut with an ax, which severed the patella tendon. He was treated immediately by his doctor, with stitches and a splint. In three weeks the union gave way, and a synovitis developed. At the second operation the patella was found retracted up the leg, with synovial fluid discharging. An effort was made to draw the patella downward; two holes were drilled in it, and through these and through the stump of the tendon I passed twelve braided silk sutures, and put on a plaster-of-Paris splint extending from toes to groin. In ten weeks I made passive motion. In three months the knee could be flexed to 45 degrees.

### Tuberculosis and Pregnancy

Dr. L. M. Allen, Winchester: Most laymen and some medical men think that pregnancy benefits the tuberculous woman. A considerable number of cases are due solely to pregnancy rendering the woman tuberculizable. The shock of labor, the loss of blood and the subsequent care of the child are a heavy strain. I have observed three cases in which the bad effect was most rapid, one patient dying sixteen days, one six weeks, and one three months after confinement. Virchow says that he never saw a case of congenital tuberculosis, and if it occurs at all it must be very rare. A child born of tuberculous parents has established a certain immunity, and if it is removed from infection it stands a good chance of not contracting tuberculosis; but it should never be cared for by its mother.

### Calculus in the Right Ureter Simulating Appendicitis

Dr. A. Murat Willis, Richmond: More than 1 per cent. of cases of supposed appendicitis turn out to be calculus. In five cases a microscopic examination of the urine disclosed blood and pus, and led to making a roentgenoscopic examination and the finding of a calculus in the right ureter. One patient declined operation, and passed the stone several months later. The advantage of the Roentgen ray in such cases cannot be overestimated.

DISCUSSION

Dr. Arpad G. Gerster, New York: In certain cases of appendicitis the reverse is true; we think that we are dealing with a kidney case when the primary trouble is in the appendix. I recall a case of a young girl with symptoms of distention of the right urinary system, but the picture was not perfectly clear. She had chills and high fever, and the loin and right hypochondriac region were exceedingly tender. Catheterization of the right ureter was negative. I operated and found the gall-bladder normal, but the kidney was enlarged. I failed to examine the other kidney and the iliac fossa. I made a lumbar incision and opened and drained the kidney. In two weeks the symptoms grew worse, the kidney disintegrated and I decided to take it out. Then I opened the abdomen through the former incision and found the appendix attached to the posterior peritoneum. It had infected the kidney by contact. I took out the kidney and the appendix, and the patient recovered.

Dr. George Tully Vaughan, Washington, D. C.: Dr. Willis did not speak of adhesions. In a boy of 20 I found the adhesions from a chronic appendix binding the ureter close to the wall of the pelvis. In a young girl the appendix crossed the ureter and firmly attached itself to the ovary.

### Dietetic Treatment of Tuberculosis

Dr. John J. Lloyd, Catawba: Carbohydrates and fats can, in a measure, be substituted for each other. We must furnish an extra supply to the cells in order to maintain nutrition, but the day of stuffing tuberculous patients is past. We aim to bring about a condition of slight overnutrition. Fat should preferably be of animal origin. Three well-balanced meals, and in addition 3 pints of milk and several eggs should be given.

### What Virginia is Doing Against Tuberculosis

Dr. B. L. Taliaferro, Catawba: Tuberculosis remains the greatest menace in our state. Last year there were 3,523 recorded deaths, and many not reported. For four years we have been waging war at the Catawba Sanatorium. There is only one private sanatorium in the state, that at "Mountain View," near Catawba. We have a well-equipped laboratory at the State Health Department in Richmond. The school-nurse and the visiting nurse are used to some extent and are active for good. The interest the corporations are taking is a hopeful sign. The Metropolitan Life-Insurance Company has visiting nurses. The Chesapeake and Ohio Railway Company and others are erecting camps for treatment. The State Colored Insane Hospital has a colony, with separate kitchens, etc. More facilities for the colored race are needed. Only those in the state prison and in the insane hospital are cared for by the state. Better facilities for diagnosis are also needed. We often have patients sent to the sanatorium in an advanced state of tuberculosis, whom we cannot admit.

DISCUSSION

Dr. L. G. Pedigo, Roanoke: One advantage of sanatorium treatment is that the patient is stopped from thinking so much about his stomach. Stomach washing, especially with silver nitrate, tends to clear up the catarrh.

Dr. Stuart McGuire, Richmond: We have no ready-made, sure-fire method of diagnosis in tuberculosis, but we should not discredit those which we have. The Roentgen ray is invaluable in certain cases in helping to clear up a diagnosis. If we sweep all these away, what have we left? We cannot wait for the pathologist to find a cavity. We must keep what we have and build on it for the future.

Dr. John J. Lloyd, Catawba: Using tuberculin in small doses is one way of studying the patient, and it is still being used by good diagnosticians. The most important single item of treatment is rest.

### Volkmann's Contracture

Dr. Stephen H. Watts, Charlottesville: I have had three cases of Volkmann's contracture caused by too tight application of splints in treating fractures. I wish to warn against this practice. Cut off the splints if necessary; it is better to have a deformity than this condition. It results from shutting off the circulation too long, which causes an ischemic myositis. Prevention is better than cure. Operative division of the flexor tendons I mention only to condemn. Shortening the bone or lengthening the tendons may be done. The former, I think, is the best. In one case I loosened up the nerves and then took out 2 or 2.5 cm. of bone. In a second case there was a fracture of the external condyle of the humerus, and a bad deformity. An incision was made from the wrist to the elbow, and I dissected up the nerves, which were badly involved. I operated two and a half months after the fracture occurred. In a third case there was a silver fork deformity. I chiseled off the upper fragment and obtained a perfect result.

### Some Methods of Preventing Puerperal Sepsis

Dr. Greer Baughman, Richmond: The prophylaxis may be placed under six heads: 1. The physician must keep clean. 2. He must have a proper armamentarium. 3. A soap-suds enema should be given before the os dilates or the waters rupture. 4. The accoucheur's hands should be treated as carefully as in major surgery. 5. No vaginal douche, before or after, should be given, except when absolutely necessary. 6. Internal digital examinations should be avoided. This is most important. The more you accustom yourselves to making external examinations, the less you will have to resort to internal examinations.

DISCUSSION

Dr. W. A. Plecker, Richmond: The midwives of the state are extremely ignorant. Fifty per cent. of the cases of confinement in the state are attended by them, which I know from being registrar of vital statistics. They have an immense number of stillbirths. Breech presentations are invariably lost by them as they do nothing to extract the after-coming head.

Dr. H. U. Stephenson, Toana: The woman should be allowed to rise to urinate, and should be carefully assisted up, in order to empty the vagina of blood and accumulations as soon as possible. Especially is this true in country practice, in which patients cannot be seen so often.

Dr. John F. Winn, Richmond: There should be a stringent law against selling the midwives ergot. I think that this is the cause of many stillbirths.

### Teaching Physiology and Hygiene in Secondary Schools

The Executive Council suggested the following: "We recommend that the Medical Society of Virginia urgently advise that the subject of physiology and hygiene be placed as a major subject in the curriculums of the secondary schools; that a committee of five be appointed by the president, to be known as the Committee of Instruction in Physiology and Hygiene, and that this committee be enlarged by inviting the following to become active members: the state superintendent of public instruction (ex officio); the president of the Teachers' Cooperative Association (ex officio), and the professor of secondary education at the University of Virginia (ex officio)."

# *Current Medical Literature*

## *AMERICAN*

Titles marked with an asterisk (*) are abstracted below.

### American Journal of Diseases of Children, Chicago

*November, VI, No. 5, pp. 289-380*

1 *Heat and Summer Diarrhea. J. Zahorsky, St. Louis.
2 *Influence of Atmospheric Conditions on Mortality of Infants Suffering with Gastro-Intestinal Disorders. A. S. Bleyer, St. Louis.
3 *Complement Fixation Reaction of Blood of Children and Infants, Using Bacillus Abortus as Antigen. W. P. Larson and J. P. Sedgwick, Minneapolis.
4 *Experiment with Raw and Heated Cow's Milk and Its Lesson. E. C. Schroeder. Bethesda, Md.
5 Roentgen Ray in Pyloric Obstruction. L. R. De Buys, New Orleans.
6 Vulvovaginitis in Children. R. M. Smith, Boston.

1. **Heat and Summer Diarrhea.**—A very thorough study by Zahorsky has convinced him that the mortality of summer diarrhea is practically the same all over the United States. The only marked exceptions are certain cities on the Western Coast. The mortality of diarrheal diseases is twice as high in the summer as in the winter. A room temperature of more than 85 F. has a detrimental influence on the sick baby.

Hyperthermia may be produced in infants when the day and night temperature is more than 85 F., but this thermic fever does not produce diarrhea or appreciably raise the mortality rate. Summer diarrhea is not the effect of high atmospheric temperature alone, but it cannot as yet be denied that excessive heat may lower the tolerance to carbohydrates and other elements of food.

Zahorsky says we must seek the cause of summer diarrhea (1) in micro-organisms whose virulence and activity may be increased in the summer; (2) in endogenic or ectogenic toxic substances of unknown nature.

2. **Atmospheric Conditions and Mortality of Infants with Gastro-Intestinal Disorders.**—Bleyer found that a definite relation between atmospheric heat and deaths among infants suffering with gastro-intestinal disturbance exists; at what degree of heat lethal effects are seen does not appear in his charts. So-called "heat-peaks" or short-lasting but excessive temperatures doubtless emphasize, but they do not dominate the summer infant death-rate; whether many of these deaths are the direct result of "heat-stroke," although easily suppos- able, has not been shown. Continuous heat shows a stronger relation, although not necessarily an immediate relation, to

deaths of infants suffering with gastro-intestinal disorders, which, as infants are now housed and fed, is very fairly constant.

3. **Complement Fixation Reaction of Blood of Children and Infants.**—In systematically examining the serum of women who have aborted, Larson and Sedgwick have found that a large number give a positive complement-fixation reaction using the *B. abortus* as antigen than when the ordinary syphilitic antigen is used.

From the work of Cotton and Schroeder we know that 10 per cent. of market milk contains the *Bacillus abortus*; there can, therefore, be little doubt that any individual using dairy products is amply exposed to infection. Bang has shown that animals may readily be experimentally infected with this organism by administering it per os. If the *B. abortus* is pathogenic for human beings, as it is for guinea-pigs, and can be transmitted through the digestive tract as is the case with cattle, we would expect infants and children to be the subjects most frequently infected. Larson and Sedgwick have to date examined the blood of 425 children by the complement-fixation method and have found at least some support of the above-expressed hypothesis. Of these 425 cases they found seventy-three positive and 352 negative reactions. In other words, the blood of 17 per cent. contained antibodies against the *B. abortus*. Agglutination tests were made in a large number of cases. They found in working with human serum, as did Holt with bovine serum, that the agglutination and complement-fixation tests run parallel. Ehrlich and Morgenroth found that the specific hemolytic antibodies would unite with the washed erythrocytes when the latter were placed in the serum and left for a few hours. By centrifuging this mixture and decanting off the supernatant serum they found that the latter had, by the contact with the blood-cells, been depleted of the hemolytic antibodies. In other words, the antibodies had attached themselves to the blood-cells and been removed with these.

The same is true of the *B. abortus* antibodies. By treating a positive serum with a suspension of the Bang bacillus, the serum, after a few hours' contact, has been found to be negative when separated from the organisms by the centrifuge. If an adequate amount of complement is then added to the sensitized bacilli and incubated for an hour, the complement will become fixed, thus indicating further that we are dealing with specific antibodies. To the pediatrist, it is of particular interest that inoculations of guinea-pigs with the *B. abortus* has been shown to produce lesions of the lymph-nodes, spleen, liver, kidney, testicle, lung and bones, and that these lesions are suggestive, anatomically, of those of tuberculosis. These findings of competent observers together with the experience that inoculation may produce epiphyseal enlargements, and 17 per cent. of positive reactions among children with anatomic lesions of the osseous system, most of them with clinical diagnoses of tuberculosis and rickets, indicate very clearly the need of further investigation.

4. **Raw and Heated Cow's Milk.**—Schroeder believes those who have studied the question impartially cannot be far from the conclusion that the infants who must, unfortunately, be fed artificially on cow's milk or the milk of a foreign species, and invalids whose diet is restricted as a whole or in part to milk, should receive properly certified milk efficiently pasteurized, or preferably, boiled, and that the general milk-supply should be made as good as the economic conditions affecting the production and handling of milk permit, and should be properly pasteurized, or preferably, boiled, under official supervision. It is constantly becoming more and more apparent that we lack the means to produce cow's milk that is constantly free from pathogenic agents, just as the number of instances are increasing which prove that seemingly healthy individuals often are dangerous disseminators of disease germs. Milk is a cause of much disease, and there are several kinds of milk that are responsible for this charge. Dirty, stale, adulterated or otherwise objectionable milk, raw, pasteurized or boiled, is and remains a menace to health. Heat, applied to milk, is not a renovating, rejuvenating or a cleansing agent; all one can expect of it is to neutralize those specific germs of disease that find their way into milk, which is the best culture medium for bacteria among all articles of food.

7. **Cerebral Syphilis.**—Henderson's paper consists of the systematic clinical analysis of twenty-six personally observed cases of cerebral syphilis, in seven of which the diagnosis was confirmed by autopsy. He says that cerebral syphilis plays an important part in the production of mental disease, and should occupy a more prominent place among the organic psychoses than it heretofore has done. The *Spirochaeta pallida* has for long been surmised to be the causal organism, but it was not until 1910 that Strasmann first demonstrated its presence in the central nervous system of an adult with acquired syphilis; the second case is reported in this thesis. Trauma, alcoholism and physical and mental strain are important contributory factors. Reinfection with syphilis is quite possible provided the initial infection has been thoroughly cured. Anatomically, three main types of cerebral syphilis are differentiated; viz., meningitis, endarteritis and gumma. Clinically, this differentiation is seldom possible, and is without practical value, as the treatment is the same in all irrespective of the type. The majority of cases of cerebral syphilis develop within the first three years after primary infection, and rarely more than ten years after infection.

In regard to the physical signs, Henderson says that the Argyll Robertson phenomenon is the one on which most weight should be laid in differential diagnosis, as it is rarely present in cases of cerebral syphilis. Other important features are: (a) an acute onset with headache, dizziness and vomiting; (b) cranial nerve palsies; (c) convulsions without loss of consciousness, but usually followed by permanent focal symptoms; (d) intactness of speech and writing; (e) absence of facial tremor. Cerebral syphilis not infrequently causes pseudobulbar paralysis, and six cases of this affection have been reported. The mental symptoms of cerebral syphilis are of the nature of those seen in acute organic reactions, and consist of confusion, delirium, amnesia, hallucinations, retention defect and a poor memory for recent events; in addition there is relatively little disintegration of the personality. The Wassermann reaction must be considered in relation with the clinical picture in each individual case; when the Wassermann reaction with the cerebrospinal fluid is negative, the diagnosis of cerebral syphilis is indicated.

It is frankly admitted by Henderson that there is no pathognomonic sign for cerebral syphilis; but if the nature and character of the onset and the above-mentioned physical and mental symptoms and signs are correlated, a disease entity is formed which has every right to be considered characteristic. Anomalous features, among which may be mentioned euphoria and grandiose ideas, and confabulatory states, are more common in cerebral syphilis than is generally recognized; special attention must be paid to the setting in which these features occur, because when occurring in a setting of confusion they mean practically nothing.

Recent statistics confirm Henderson in the opinion that the prognosis of cerebral syphilis, as compared with other organic affections of the nervous system, is relatively good; the most favorable cases are those which develop soon after the primary infection, and those of a meningitic or gummatous type. Mercury, no matter in what form administered, is an exceedingly valuable drug in the treatment of syphilis, provided it is given in a systematic way. The best results are, however, probably obtained by combining mercurial and salvarsan treatment. Potassium iodid acts simply as an eliminative agent, and has no specific action on the *Spirochaeta pallida*. The only safe treatment is prophylaxis.

8. **Unusual Forms of Status Epilepticus.**—In the past ten years, in private practice, Clark has known three of his severest cases of epilepsy with status attacks to enjoy complete remission or cure from any manifestation of the epilepsy for three, five and eight years, respectively, and this, too, occurred without sedative medication being employed. One patient had as many as 120 grand mal attacks a day and fever of 105 F. during the status. He states, however, that all of these recoveries occurred in cases of short duration and in which no mental changes had taken place. They were, by all strict tests, however, true epilepsy as ordinarily considered.

15. **Occupation in Mental Diseases.**—Among no class of patients are the beneficial effects of employment more marked than among the insane in our hospitals. Employment as a remedial agent has been made use of in the Taunton State Hospital from the time it was opened in 1854 until the present time, a period of nearly sixty years. Goss considers the results obtained in consequence of the employment of patients in this institution during this long period.

28. **Ammoniacal Diaper and Its Correction.**—The detection of a noticeably ammoniacal odor on the diapers of an infant, especially if the diaper has been recently removed, and the phenomenon is repeated, Southworth says, points to a definite disturbance of metabolism. Furthermore, this ammoniacal odor may be regarded to some extent as an index of the disturbance, since it tends to disappear when the food has been adjusted so as to allow of more perfect metabolism. For the present, the fat of cow's milk seems to be the more frequent offender when given in excess of the normal capacity, or in cases of fat intolerance when given in excess of the individual's capacity. Southworth insists that more attention should be paid than has been paid in the past to the ammoniacal diaper as a clinical sign. The great desideratum in imparting to others the principles of infant feeding is to be able to point out definite indications for changes in the composition of the food. An odor of ammonia on the diaper furnishes such indication, for it at once directs attention to a disturbance of metabolism, presumably traceable to an actual or relative over-feeding with the fat of cow's milk.

29. **Influence of Diet on Gastric Motility in Infants.**—Ladd states that the casein of cow's milk, when given in high percentages, has a decided action in prolonging the emptying time of the stomach. If this casein is precipited outside the body, the emptying time is greatly accelerated. The presence of fat has no retarding action, and in some cases seems to favor the exit of the stomach contents. Ladd is of the opinion that there is some reason to believe that barley starch renders the food more easy of exit.

33. **Treatment of Hernia in Infancy.**—Experience leads Hoguet to say that operation is always indicated in otherwise healthy babies that have a hernia that cannot be perfectly held in place by a truss—and the word perfectly is emphasized—that the operation itself is without danger and the anesthetic, if properly given, is of very little danger. All patients with strangulation or persistent incarceration must, of course, be operated on as soon as possible. The treatment of umbilical hernias in infants is comparatively simple. If treatment is begun early enough, that is, when the child is only a few months old, practically all of these patients can be cured by applying a small pad over the hernia and holding it in place with a piece of adhesive plaster, which is carried all the way around the body. The plaster has to be renewed every ten days or so, and it is very important that there be no interruption in the treatment. The pad and plaster generally have to be kept on for five to ten months before the child is cured. In children over two years of age this method of treatment should be given a trial for a few months, and then if not successful operation is indicated. Either the ordinary suture by layers or the horizontal overlapping operations give very excellent results in children.

54 Idem: Relation between Lysis and Proteolysis of Pneumococci. J. W. Jobling and S. Strouse, Chicago.

41. **Blood Destruction and Regeneration.**—After splenectomy, Musser and Krumbhaar state that anemia usually develops quickly and reaches its height in from three to six weeks; then with gradual improvement the blood-picture

approaches the normal after about three to four months, with complete return to normal in five to ten months. Accompanying this is marked leukocytosis reaching its height in twenty-four hours but persisting to a slight degree for several months. Variations, however, may occur, in that the anemia may develop slowly and be of slight degree, or the reparative process may be delayed and up to ten months incomplete. The anemia is, however, inevitable, as is also, later, some degree of repair.

42. **Idem.**—The increased resistance of the red blood-corpuscles characteristic of the splenectomized animal, Pearce and Peet found, is as evident one year after removal of the spleen as it is at earlier periods. So also is the decreased tendency to jaundice after the administration of hemolytic serum. The increase in resistance of the red cells cannot be explained on the basis of an increase in reticulated cells in the circulating blood.

43. **Relation of Pulmonary and Bronchial Circulation.**—The most striking point brought out in this study by Ghoreyeb and Karsner is that as long as a definite pressure is maintained in either the pulmonary or bronchial circulations, the admixture of bloods is extremely limited. If, however, in either system the pressure sinks to zero the possibility of supply by the other system becomes evident. It takes much longer for the mass injected through the bronchial arteries to penetrate to all parts of the lung than when the mass is injected through the pulmonary artery; but when accomplished, the injection reaches to all capillaries including those of the pleura, the only vessels remaining uninjected being the larger trunks of the pulmonary artery. On the other hand, the injection of the bronchial vessels by way of the pulmonary arteries is not complete with normal pressure, but occurs rapidly when a high pulmonary pressure is employed. It is therefore probable that either circulation can suffice for the simple nutritive demands of the lung if the other system is interfered with.

It has been shown that embolism of the pulmonary artery, without other circulatory disturbance, does not lead to necrosis of the affected area of the lung, but it is probable that the preservatioin of circulation is not due to collateral bronchial circulation so much as to the free anastomosis and early division into capillaries of the pulmonary artery. In support of this statement is the fact that the appearance is not altered when the bronchials are ligated at their origin. The same ligation shows no subsequent interference with the nutrition of the bronchi up to a period of five weeks, demonstrating that the pulmonary circulation is sufficient to provide for the nutrition of the bronchi. If, however, as Virchow has shown, the pulmonary artery supplying an entire lobe be occluded, the bronchial circulation can and does suffice for the nutrition of the lobe.

In the case of the occlusion of a branch of the pulmonary artery the pressure in the area interfered with does not sink to zero because of the collateral circulation in this area; whereas, if the main trunk is occluded no collateral supply is available, the pressure sinks to zero, and the bronchial artery becomes available as a source of blood-supply. From these studies it would appear that the part of the lung tissue not in intimate contact with oxygen in the air is supplied by oxygenated blood of the bronchial arteries, and that the tissues through which the pulmonary blood circulates take up whatever organized nutriment they need from the pulmonary blood and possibly provide for their oxygen and carbon dioxid interchange (which must be very slight) either directly with the alveolar air, or by finding sufficient oxygen in the venous blood of the pulmonary artery.

44. **Infarction.**—The same laws for mixture of the blood of bronchial and pulmonary vessels laid down in connection with the circulation in the lung in general, was found to apply also to the circulation in an area of embolism; i. e., there is no notable mixture of the bloods until the pressure in the one system or the other sinks to zero. Simple embolism of the pulmonary artery results in lowered pressure in the embolic area, the pressure, however, not sinking to zero unless the blood-supply of an entire lobe is cut off. The circulation in the embolic area may be improved by increasing the pressure in either the pulmonary or bronchial arteries, but so long as the two circulations are going on, extremely high pressures are not sufficient to restore the circulation to normal in the area of embolic congestion. With normal pressures in the two vascular systems, an area of pulmonary embolism involving less than the entire lobe receives its blood-supply almost entirely from the rich anastomosis of the pulmonary artery between its own branches, and only when the bronchial pressure is raised to an extremely high point does the blood from this vessel play a notable part in the circulation in the area.

47. **Pneumonic Lesions Caused by Bacillus Megatherium.**—The saprophytic *Bacillus megatherium*, Wollstein and Meltzer found, produced a definite pulmonary lesion which in gross appearance resembled the lesion of lobar pneumonia. The lesion was one of intense leukocytic exudation which, as in some other cases of experimental lobar pneumonia, did not invade the framework of the lung. But the exudate contained no fibrin. There were practically no bacilli, either in the heart's blood or in the lung. The growth of two colonies from one of the cases hardly changes the rule. The lesion did not progress after twenty-four hours; nor did it show a definite increase in extent or intensity with the increase in quantity of the injected cultures. The resolution of the exudate began practically at the end of twenty-four hours and was far advanced on the third day. Although there was considerable leukocytic infiltration there was no phagocytosis apparent twenty-four hours after inoculation. Taking all the facts into consideration, the authors gain the impression that the lesion produced by the saprophytic *Bacillus megatherium* differs only quantitatively from that produced by an avirulent pneumococcus. The fact stands out prominently that a saprophytic bacterium is capable of producing a pneumonic lesion similar in gross appearance to that of mild lobar pneumonia. The authors suggest that it is not improbable that other saprophytes may be capable of producing pneumonic lesions which, in specific instances, may resemble lobular pneumonia.

48. **Lesions Produced by Virulent Streptococci.**—The several investigations which Wollstein and Meltzer have carried out seem to show conclusively that in general the streptococcus causes a lobular pneumonia which, besides the leukocytic intra-alveolar exudation, is characterized by a leukocytic infiltration of the lung framework, and that the pneumococcus causes a lobar pneumonia, which is practically free from leukocytic infiltration of the interstitial tissue of the lung. Furthermore, a virulent pneumococcus causes a lesion in which fibrin is a prominent element in the exudate and that element distinguishes the exudate sharply from the exudate of the lesion caused by a virulent streptococcus in which fibrin is present only in moderate amount. It distinguishes it in a still more striking manner from the exudates of the lesions caused by non-virulent pneumococci or streptococci, in which fibrin is present only in very small amounts. It seems that the formation of fibrin is connected in some specific way with the pneumococcus on the one hand, and with the virulence of the organism on the other. For even with the relatively small amounts of fibrin present in the exudates of lesions caused by the streptococcus there is a perceptible difference in the quantity according to the virulence of the organism. Whether fibrin is a means which enhances virulence, or whether it is a reaction product against it, the authors' experiments so far do not entitle them to discuss.

49. **Disturbances of Heart-Beats in Dog.**—Robinson and Auer found that anaphylactic shock in the dog, caused by the intravenous injection of horse-serum into sensitized animals, may produce definite cardiac disturbances which are revealed by the electrocardiogram. These cardiac changes consist of disturbances in conduction of the heart impulses, abnormalities in the ventricular contractions, and other unusual disturbances of the mechanism of the heart-beat. They come on very quickly after the injection of serum and may be of short duration, and are not obtained during anti-anaphylaxis. They are not the result of the marked fall in blood-pressure which

occurs, nor does the central cardiac inhibitory mechanism play a part in their production. These cardiac disturbances apparently are a definite primary expression of anaphylactic shock in the dog. The right ventricle seems to be more affected than the left.

50. **Cultivation of Trachoma Bodies.**—An organism was isolated by Noguchi and Cohen and studied in pure cultures from cases of conjunctivitis accompanied by the so-called trachoma body inclusions, as well as from a case of old trachoma without inclusions. This organism was not found in the cultures made from other forms of conjunctivitis in which the inclusions were absent. The organism presents the morphologic features characteristic of so-called trachoma bodies. It undergoes an early transformation, during which the forms known as initial bodies appear, and a later change, during which forms resembling elementary granules arise, while certain intermediate forms between these occur simultaneously. No definite cell inclusions could be produced in monkeys by inoculating pure cultures of the organism.

52. **Comparative Viability of Pneumococci.**—According to Gillespie, pneumococci, when freshly isolated from the body, are able to live and multiply when a small number of them are inoculated into a small amount of broth. If, however, the inoculations are made in large amounts of broth, many more bacteria must be inoculated in order that they may grow. It requires much smaller numbers of pneumococci to start a growth on agar than are required to start a growth in broth. This predilection for solid medium disappears when the bacteria are grown for some time outside the body. This phenomenon is not dependent on differences in chemical composition between the two media employed or on the presence of more available oxygen in one case than in the other. Gillespie suggests that it is probably dependent entirely on physical differences in the two kinds of media, and bears some relation to the differences in possibilities for diffusion in the two media.

72. **Roentgenoscopy in Pyloric and Duodenal Ulcer.**—Spastic hour-glass stomach is described by Case as a sign of duodenal ulcer. He reports sixteen operated cases of duodenal ulceration in which this spastic indrawing, high up on the greater curvature, was noted. In a number of other cases of duodenal ulceration (operated) no spastic indrawing was observed. In at least two other cases, the patient was examined on three successive mornings. On the first and third mornings, the spastic indrawing was noted. On the second morning, although the patient was observed repeatedly, no such spastic indrawing could be seen. In differentiating between a spasm due to gastric ulcer and spasm due to duodenal ulcer, Case has observed that in duodenal ulcer, there is not a point of pain on pressure over the lesser curvature corresponding to the level of the spastic indrawing; on the contrary, there is pain on pressure over the duodenum; and manipulation of the duodenal region increases the depth of the spastic indrawing. This spastic manifestation, however, has also been observed in one case of exophthalmic goiter and in some cases of appendicitis and in at least half a dozen cases of gall-stones in which, at operation, the surgeon was unable to find any duodenal or gastric ulcer.

94. **Device for Blood-Vessel Anastomosis.**—Two metal rings and a holder are used by Christian and Sanderson. The thickness of the rings varies with their diameter, but even the largest size is not thicker than the lead in an ordinary pencil. The inside diameter of the rings corresponds to the outside diameter of the vessel being operated on. From one lateral surface of each ring project five or six very small bearded points, not longer than 1/16 to 1/8 of an inch. Short pieces of a dentist's brooch make admirable points. Two pieces of small, pliable wire ¼ inch long project out from opposite sides of the convex border. The holder is an instrument similar to a small dressing forcep, with the simplest pin-lock, so that two parts may be attached or detached at any degree of opening of the blades. The tip of each half of the holder is made with a clip and slip-cuff, so that a ring of any size may be held firmly, the ring being held edgewise. Using a holder, the ring is passed over the cut end of the vessel, which is then everted and pinned to the ring by the use of a dissecting forcep or the finger tip; the little bearded points holding it nicely. The other cut end is likewise everted and pinned to the other ring. The two parts of the holder are now fitted together and closed and locked, which brings the rings into perfect apposition and with any degree of pressure desired. A twist of the soft wire binders completes the anastomosis and the holders are removed.

95. **Transmission of Pellagra.**—In July, 1910, a typical, fatal case of pellagra presented itself for necropsy to Harris. The necropsy showed only lesions consistent with pellagra, and no other evidences of concomitant disease were present. Portions of the brain and cord, and the lesions of the gastro-intestinal tract and skin were collected. Emulsions were prepared and Berkefeld filtrates derived therefrom. These were inoculated in large quantities subcutaneously, intravenously and intracranially. After an unexpectedly long period of incubation this animal developed clinical signs and symptoms in accord with those of pellagra, and finally died. At necropsy no other causative factor for death, aside from the lesions found in fatal pellagra, was present. Microscopic study corroborated the gross findings, and the skin especially presented the hyperkeratosis and pigmentation identical with that found in the skin in human pellagra.

The experiment was not repeated until a similar typical, fatal human case became available. In this instance the ileum showed especially clear-cut lesions, presenting marked hyperemia, a mucous exudate and miliary ulcerations. These areas especially were selected and formed the greater part of the emulsion. Injections were given subcutaneously, intravenously and intracranially of a filtrate of this mixture procured through a Berkefeld No. N. Two months later this monkey was reinoculated in a similar manner and with similar materials. After two months of observation he developed a diarrhea, inflammation of the tongue, loss of appetite and presented erythematous skin lesions over the bridge of the nose, which spread in wing-like manner over the cheeks and under the eyes. He became emaciated and listless. Lesions, characterized especially by their symmetry of location and shape, developed on the conchae of both ears, the shoulders, arms and dorsal surfaces of the hands. These gradually became pigmented, assuming a deep brown color, and desquamation in scales and placques finally occurred. Across the neck, just on a line with the clavicles, a band-like lesion developed similar to those already described, and gradually merged into the lesions on the shoulders. The fact that the intestine formed the greater part of the filtrate used in this last experiment suggests the possibility that the stools may play some part in the transmission of the disease.

96. **Spinal Anesthesia.**—In Babcock's experience ether and spinal anesthesia have been about equally dangerous, ether from exigencies compelling a profound narcosis or an imperfectly trained anesthetist; spinal anesthesia from an unwise selection of patients and an imperfect knowledge as to the physiologic action of the drug. With careless or unskilled use, Babcock says, spinal anesthesia is doubtless much more dangerous than ether. The morbidity of spinal anesthesia as expressed by nausea, vomiting, headache, backache, postoperative pain, and albuminuria is less than that from ether. Ocular palsy may result from spinal anesthesia where contaminated or deteriorated solutions are used. A lateral deviation of the needle with injury to a nerve root may be followed by severe neuritis and secondary palsy. Secondary degeneration of the spinal cord from the chemical action of stovain, properly introduced in human beings, for purposes of spiral anesthesia is doubted.

Functional or neurotic symptoms occur after spinal anesthesia as they do after etherization, and may, to the annoyance of the surgeon, be attributed by the patient to the injection. If a steel needle be used it may be broken under the skin during the injection. Danger symptoms may follow if the patient be moved immediately after the injection or if the proper posture to prevent the anesthetic from reaching the upper nerve roots be not maintained for at least one-half hour after the injection. Repeated intradural injections seem to be harmless. Babcock warns that spinal anesthesia is dangerous in circulatory subtension, conditions greatly depressing the respiratory centers, and shock, collapse, advanced myocardial disease, and large intrathoracic effusions. It is more dangerous for operations on the upper abdomen than those on the lower. It does not obviate the danger of sudden cardiac arrest in operations for large uterine fibroids.

Babcock insists that the newer methods of anesthesia, including spinal anesthesia, nitrous oxid oxygen, intravenous anesthesia should have their use restricted to selected patients by those who have properly qualified themselves. If the patient cannot be properly watched for one hour after the injection, if the operator does not understand the dose and mode of diffusion of the drug, or if he is unprepared to meet emergencies, then spinal anesthesia should not be employed For general indiscriminate use ether remains the standard anesthetic despite its many drawbacks.

112 Experimental Entamebic Dysentery. E. L. Walker and A. W. Sellards, Manila.

105. **Intestinal Parasites.**—In a series of 500 consecutive necropsies on people of all ages in Manila, *Ascaris lumbricoides* occurred in 41.2 per cent., *Trichuris trichiura* in 34.4 per cent., hookworm in 16.6 per cent., *Taenia saginata* in 0.2 per cent., *Cysticercus cellulosae* in 0.2 per cent., *Oxyuris* in 1 per cent., *Clonorchis sinensis* in 0.4 per cent., *Schistosoma japonicum* in 0.2 per cent., malaria in 5 per cent., and amebic colitis in 5 per cent. The manifestations of ascariasis have been the presence of ascaris in the liver as the result of both antemortem and post-mortem wanderings, and its possible action as the exciting factor in one case of widespread hemorrhages. One clinical case of *ascaris* in the appendix has been encountered. *Ascaris* has not been found less frequent in febrile than in other cases. Trichuriasis occurred in 33.9 per cent. of the males and 35.4 per cent. of the females; 15.53 per cent. of the patients under 15 years of age and 40.1 per cent. of the patients above that age harbored *trichuris*. Two clinical cases of appendicitis in which *trichuris* was found in the appendix have been encountered. One case has been described exemplifying the frequently encountered hemorrhages in the submucosa of the intestine associated with the presence of the hookworm. One *Taenia saginata* was the only tapeworm encountered. The infrequence of *Taenia solium* in human cases as compared with the great frequence of *cysticercus* in hogs in the Philippines has been deemed noteworthy. One case of *Cysticercus cellulosae* in the human cadaver has been reported in detail.

109. **Axillary Teratoma.**—In Gilman's case, a swelling was noted under the right arm shortly after birth. This swelling increased slowly but steadily in each diameter. At the age of 7 the patient had a slight fever and the tumor became red and increased noticeably in size. At that time, occupying the right axilla and limiting considerably the movements of the

arm in all directions was a tumor measuring about 12 cm. in diameter, with a general spherical form. The growth as a whole was soft and elastic and movable, although evidently attached to the apex of the axilla and upper portions of the chest wall; was not tender nor painful. The skin over the mass was more or less adherent in several linear areas, one of these on the external surface being reddened and inflamed. The vessels of the skin over the growth showed great distention and considerable venous stasis. The tumor evidently contained fluid under the considerable tension, and over the posterior portion of the wall of the cyst gave a sensation as though considerable fibrous thickening had taken place with probably a deposition of some mineral salts. It was removed. The growth shelled out readily over nearly the entire surface, difficulty being experienced only in the apex of the axilla where the artery, several branches of the vein, and most of the nerve branches were enveloped in the fibrous capsule of the cyst and over the fifth rib, the periosteum of which was intimately connected with the wall. A small portion of the fluid of the cyst was aspirated immediately after the specimen was received, and was seen to be clear and yellowish in color. The pathologic examination showed it to be a teratoma of mesodermal origin or autochthonous monophyllic teratoblastoma of mesodermal origin.

**3. Operation for Inducing Artificial Pneumothorax.**—Woodcock has tried both puncture and the incision method, and prefers the puncture. The nitrogen is generated from the air as required, by means of a pyrogallate solution. It can be warmed by filling with hot water the bottle into which it is to pass; to maintain the heat a hot water jacket may be used. It is an additional precaution against sepsis to fill this bottle with a solution of hydrargyrum perchloridum, 1 in 5,000. The manometer is so constructed that it acts as a safety valve, allowing no greater pressure than 10 in. of water. It permits of direct communication with the patient, not merely through the nitrogen jar, so that the actual pressure within the pleura can from time to time be controlled.

**5. Effects of Emetine on Abscess of Liver.**—The noteworthy points of this case are: The cavity in the liver, which at the time of operation contained 1½ pints of pus, was found nine days later to have a capacity for only 4 ounces, while a very rapid advance of fibrosis was proceeding through a thickness of tissue that measured ¾ inch. Several separate foci of pus had been rendered inert and crystallized into solid, buff-colored islets, which disclosed microsopically the very beginnings of fibrosis. More evacuations of pus and local treatment could not account for this latter phenomenon, even if they did for the former.

**9. Radium and Inoperable Cancer.**—Warden's conclusions are as follows:

1. Simple obstruction of the intestinal lumen must be clearly distinguished from strangulation. In the latter, death ensues long before the obstruction to the onward passage of intestinal content has become a factor of importance. 2. Simple obstruction high up in the intestine differs from that lower down, chiefly in the great loss of intestinal secretions by vomiting in the former, compared with the latter, where the secretions are reabsorbed above the obstruction. 3. Absorption of poisons from the content of the obstructed intestine is not the leading factor in producing the symptoms of acute ileus. 4. The danger of allowing the content pent up above an obstruction to flood the empty intestine below has probably been exaggerated. 5. Peritonitis plays no part in causing death in the majority of cases of simple intestinal obstruction; in cases of strangulation, however, it may undoubtedly be a factor in the later stages. 6. In all varieties of intestinal obstruction the bowel content is infective. 7. Splanchnic paresis with depletion of the systemic circulation is the main factor in producing the symptom-complex of acute intestinal obstruction. In treating this factor, besides the operative relief of the obstruction, copious subcutaneous infusions of saline and dextrose solutions are of immense value. Clinically, the administration of pituitrin is found to be a valuable adjuvant. 8. The prompt relief given by enterostomy in cases of simple obstruction of the small intestine in the human subject is to be explained, not so much by the relief from toxic absorption as by the breaking of a vicious circle, the intestinal distention causing a paresis of the splanchnic vessels, and vice versa. By relieving the intestinal distention the splanchnic vessels are allowed to regain their tone, and the depletion of the systemic circulation is arrested. 9. The operative treatment of intestinal obstruction should be as conservative as possible; only on imperative indications should the intestinal lumen be opened. The danger of a postoperative peritonitis from the slightest soiling is much greater than that of toxic absorption from a loaded bowel.

31. **Necrosis of Cortex of Kidneys.**—To the ten cases of symmetrical necrosis of the cortex of the kidneys reported in the literature Rolleston adds the eleventh case. The ages of these eleven patients varied between 22 and 48 years. Nine were multigravidae, one was a primipara, and in one case there was no statement. In one case only was there a live birth and in that instance there were live twins. The exception to the statement that symmetrical necrosis of the renal cortex is a puerperal manifestation is that in very rare instances embolic infarction may be so extensive as to produce this anatomic lesion.

The clinical features are remarkable in resembling in the main those of calculous obstruction of both ureters rather than those usually regarded as characteristic of non-obstructive anuria. Uremic manifestations were absent in some of the reported cases and when present were usually comparatively slight. Dyspnea occurred in three cases. Convulsions are recorded in six cases. But in two out of these six cases the convulsions occurred only before the uterus was emptied and therefore cannot be so distinctly correlated with the anuria as in the other four cases. In two cases convulsions occurred after delivery; in one case both before and after delivery. Of the five cases in which convulsions did not occur the kidneys were previously healthy in three, showed endarteritis without renal fibrosis in one and chronic nephritis in one. Of the six cases in which convulsions occurred the kidneys were previously healthy in two; in one case—a woman of 22, in whom twelve fits occurred before delivery, there was very slight endarteritis only, and in the remaining three cases there was no change. Anuria is a striking feautre in nearly all these cases.

The morbid lesions are remarkable in showing symmetrical necrosis of the renal cortex with thrombosis of the renal vessels supplying the cortex, usually of the interlobular arteries in the middle zone of the cortex. In some of the cases there was a narrow rim of unaltered cortex immediately under the capsule. Its escape appears to depend on the anastomosis between the arteries in the capsule of the kidney and those supplying the perirenal fat, and resembles the condition often seen in ordinary embolic infarction of the kidney.

34. **Chief Function of Peritoneum.**—Recognizing the fact that the chief function of the peritoneum is to combat bacterial invasion. Howell suggests that the symptoms of typhoid are due to the infection of the peritoneal cavity by the *Bacillus typhosus*, the sloughing Peyer's patches being marks of their disputed but victorious passage. A boy's bilious attack, he claims, is due to peritoneal infection, also the summer diarrhea of children. Some of the cases of "vicious circle" after gastrojejunostomy are instances of septic peritonitis. Some of the failures of gastrojejunostomy are due to the fact that the operation has been performed, not on account of organic pyloric obstruction or gastric or duodenal ulceration, but in cases of chronic infection of the peritoneal cavity, the source of which was not found; the poison therefore continuing, the liver and stomach continued their necessary work of excretion. The abdominal incision and manipulation of the viscera, by temporarily draining the peritoneum and causing a fresh sharp effusion of serum, ensured them a short respite. The liver and stomach, he continues, by no means escape themselves scot free in the performance of these vital duties. In cases of acute infection the liver cells, especially those in the outer part of the lobule, on which the greatest stress would fall, show fatty degeneration; in the more chronic forms they die out entirely, and their place is taken by fibrous tissue. Again, the muscular coats of the stomach, constantly bathed in toxic lymph passed into it by the visceral endothelium, would gradually become atonic, causing a chronic dilatation of the organ; sometimes this lymph would actually contain organisms which the peritoneum and omentum had imperfectly dealt with, and these again, during the time that they found themselves in the submucous tissue, would produce necrosis, and begin the mischief of ulceration. In cases of still greater stress on the peritoneum, as in some cases of puerperal fever, ruptured gangrenous gall-bladder, etc, the organisms set up a general condition of acute phlegmonous gastritis.

35. **Transmission of Disseminated Sclerosis.**—*Bullock* has succeeded in producing paralysis of the limbs in four rabbits out of five by injecting cerebrospinal fluid, withdrawn under rigidly aseptic conditions from a case of disseminated sclerosis, subcutaneously into rabbits. The fluid was found to be potent after exposure to a temperature of 0 C. for fourteen days, and after being filtered through unglazed porcelain. Histologic examination of the spinal cord revealed a complete reproduction of the appearances found in the human subject, viz.: (1) vascular engorgement and fragmentation of the myelin sheath in the early stages; (2) areas of degeneration throughout the cord, demonstrable by the Marchi and Weigert-Pal methods, in the latter stages of the disease. Whether the cerebrospinal fluid obtained from a second case of the disease would have produced paralysis in two wild rabbits or not could not be determined owing to the premature death; in the case of the other two animals the fluid was not potent in producing paralysis. A cat which was inoculated with fluid obtained from the first case remained active and healthy for nine weeks.

If, Bullock says, one assumes that disseminated sclerosis is a definite entity and that the first patient from whom cerebrospinal fluid was obtained was an instance of the disease, one is bound to conclude that the cause of the disease is either a virus (organism) or a water-soluble poison found in the cerebrospinal fluid. While the final demonstration of the first conclusion is not yet obtained the balance of probability lies in its favor. Thus the fact that paralysis occurs from fourteen to twenty-one days after inoculation is fairly strong evidence against a non-living poison. Against all this, however, must be placed the possibility that the disease called disseminated sclerosis is not individual, but that it may be a symptom-complex which may be produced by two or more causes. The fact that the cerebrospinal fluid obtained from the second case failed to cause paralysis in four wild rabbits lends some support to this possibility. One must, however, attach some importance to the fact that wild rabbits were used in these experiments, whereas tame ones were employed in the first.

45. **Non-Cancerous Stenosis of the Colon.**—In the case described the symptoms were those of Hirschsprung's disease in a woman of 75, but necropsy disclosed merely stenosis from old inflammatory lesions, possibly tuberculous. True Hirschsprung's disease involves congenital malformation of the colon.

48. **Transplantation of Kidneys.**—Villard and Perrin give an illustrated description of the findings in three dogs after transplanting one of the animal's kidneys to some other point. The operation proved a success in only one instance; the left kidney had been transferred to the neck and connected with the primary carotid artery and the external jugular vein with the ureter sutured to the skin. The kidney kept up its functioning but showed signs of mild inflammation when the animal was killed two months later. It had evidently become infected through the ureter from the skin. A kidney from other dogs was transplanted into the animal in nine other experiments. The results at first were excellent, the kidney functioning nearly normally, but the implanted kidney was absorbed in time or it sloughed away. Attempts to transplant a kidney from a cat to a dog, goat to dog, etc., invariably failed.

49. **Treatment of Hydrocele.**—Gomoiu has applied with excellent and permanent results in twenty-five cases a method of treatment utilizing the inguinal canal. This leaves the scrotum intact and acts exclusively on the direct seat of the lesion in question while the conditions for healing afterward, he says, are ideal. It is easy to work the top of the tumor up into the incision in the inguinal region, evacuate it and evert or excise the vaginalis, and then push the testicle back into its place. It is not necessary to puncture through the scrotum first. He has operated by this inguinal route in fifty-three cases for varicocele, hydrocele, resection of the epididymis or castration. Phocas of Athens has also been using the inguinal route for two years to his constantly increasing satisfaction.

57 The Temperature in Tissues during Application of Superheated Air, Diathermia or Electrocoagulation. M. Grunspan.
58 *Operative Treatment of Vicious Ankylosis of the Knee. P. Brocq. To be continued.

55. **Congenital Misplaced Kidneys.**—Lejars and Duval discuss the mistakes in diagnosis for which a displaced kidney may be responsible when the anomaly causes no symptoms. They have encountered two such cases recently, the displacement of the kidney being unsuspected before the operation. In one the operation was done for torsion of a pedunculated fibroma in front of the uterus and a tumor found in front of the spine proved to be a kidney, somewhat atrophied and sclerous, which was safely removed with the fibroma below. In the second case the operation was done for ileus supposed to be the work of a neoplasm, but the growth seen on roentgenoscopy proved to be the kidney in the left iliac fossa, compressing the intestine. In other cases on record the displaced kidney interfered with menstruation or was the seat of pains during the menstrual congestion. In others the displacement of the kidney was masked by disease in the uterine adnexa. The main point in diagnosing is to bear in mind the possibility of a displaced silent kidney. In eleven cases on record the diagnosis was correctly made. The discovery of other malformations is an aid to the diagnosis of dystopic kidney. Also the discovery of a depression suggesting a hilus at some point in an abdominal tumor seen on roentgenoscopy, especially when pulsation can be palpated at this depression. There is always a possibility that a tumor may prove to be a supernumerary kidney, such as MacArthur has reported. Other aids in diagnosis are the difference in the depth to which the ureter catheters can be introduced, and the albuminuria and red corpuscles found in the urine half an hour after the "tumor" has been palpated and lightly kneaded; if there has been preceding albuminuria, it is increased under this. This increase two, three or eleven-fold in the albuminuria permitted recognition of the misplaced kidney in four cases in Fedoroff's service at St. Petersburg. If the kidney is atrophied and sclerous and the existence of an apparently sound mate is determined, nephrectomy can be done at once when the displaced kidney is encountered as an operative surprise. But under other circumstances it is better to postpone the nephrectomy until the functional capacity of the other kidney can be ascertained. In three cases on record necropsy showed that there was no second kidney.

56. **Bending of the Radius.**—Binet and Mutel give an illustrated description of a case of radius curvus and expatiate on the ease, simplicity and perfect results of operative correction of the deformity when the bone is cut across slanting and forcibly straightened. The correction is maintained by a plaster gauntlet, the hand turned toward the ulna, the thumb upward, with extreme extension of the hand on the wrist. If these points are observed the deformity can be corrected without shortening of the arm.

58. **Operative Treatment of Crippled Knee.**—This instalment of Brocq's long article discusses ankylosis of the knee with flexion, and means to correct the deformity without attempting to put an end to the ankylosis. Various other forms of crippling of the knee are also discussed and the attempts on record of grafting whole joints. Fifteen illustrations accompany this part of the monograph.

59. **Local Disinfection of Parturient.**—Leidenius devotes over seventy-five pages to the account of his experiments and experiences at Helsingfors, with tabulated details of conditions in fifty cases in which the child was born without any attempt at disinfection and six other groups in which various methods were applied. The impression from the total 150 cases is decidedly in favor of efficient disinfection. The ordinary methods in vogue do little good, but if the vagina is rinsed out with boiled water and a weak disinfectant and the vulva is shaved and painted with tincture of iodin, the danger of infection later is materially reduced. Prophylactic vaginal

douches are particularly useful when they can be applied with aseptic technic.

### Archiv für Verdauungs-Krankheiten, Berlin

64 *Perforated Diverticulum in the Esophagus. F. Egle.
65 *Percussion of the Liver (Zur perkutorischen Untersuchungsmethode der Leber.) W. Orlowski.
66 *Multiple Cancer of the Intestines. E. v. Muralt.
67 *Ichthyol for Lavage of the Stomach. (Verwendung des Ichthyols zu Magen-Spülungen.) A. Conti.
68 *Estimation of Functional Capacity of the Pancreas. M. Lifschütz.
69 *Determination of Free Hydrochloric Acid in the Stomach without the Stomach Tube. (Beiträge zur Untersuchung des Mageninhalts ohne Sonde.) H. Friedrich.

**64. Perforation of Esophagus Diverticulum.**—In the two cases reported by Egle, the diverticulum had evidently developed from traction by shriveling processes in the mediastinum. In each instance the diverticulum developed in the anterior wall of the esophagus above the bifurcation and caused no symptoms of any kind until perforation occurred, entailing suppuration in the mediastinal tissues, resulting in purulent pericarditis in one case and in perforation of the trachea and aspiration pneumonia in the other, both fatal. In the latter case there was a cancer at another point in the esophagus which suggests that possibly the cancer may have originated in another diverticulum not recognized at necropsy.

**65. Percussion of the Liver.**—Orlowski calls attention to the instructive findings possible when threshold or orthopercussion is applied to the liver, that is, percussing so lightly that the findings are just at the threshold of audibility. The percussion is done in the sagittal direction. He has thus examined the liver in 288 men and 212 women, applying the percussion about 1,200 times in all. In 892 investigations, the lower margin of the liver as thus outlined corresponded with the palpation or operation findings in 83.5 per cent. of the cases. The percussion was applied in connection with other diagnostic measures. The various factors, such as filled bowel, etc., liable to interfere with the percussion findings are discussed.

**66. Multiple Cancers in Boy.**—The boy of 13 had had symptoms four years before which suggested tuberculous peritonitis at the time. Later ileus developed and the boy died from increasing weakness the second day after the operation. Necropsy revealed several cancers in the intestines, the largest in the ascending colon, the ileum and jejunum studded with about forty nodules; all the growths were typical cylinder-celled cancer.

**67. Advantages of Ichthyol for Rinsing Out the Stomach.**—Conti has been using for ten years a 10 per thousand solution of ichthyol for rinsing out the stomach in case of gastritis or malignant disease, and has found the results very satisfactory. He poured the fluid into the stomach and left it there for fifteen to twenty-five or thirty minutes, leaving the stomach-tube in place in the meanwhile. The patients displayed a surprising tolerance for it, and the toxic coefficient of the stomach content was materially modified by the ichthyol, as he explains in detail.

**68. Tests of Functional Capacity of the Pancreas.**—Lifschütz applied various tests to forty-two persons to determine the functional capacity of the pancreas, and devotes over forty pages to description of the findings and the lessons to be learned therefrom. The findings in the stool were more instructive and reliable than those in the gastric juice after an oil test-breakfast, but the best plan is to combine the two methods. Negative response to the casein digestion test applied to the stool is more instructive than a positive result, as erepsin and certain bacterial ferments are able to digest casein to some extent. Vigorous digestion of casein by stool extract is strong testimony in favor of normal functioning on the part of the pancreas. He found no essential difference between the action on albumin of trypsin, erepsin and certain bacterial ferments—all of these digest casein, but erepsin has no action on egg albumin.

**69. Examination of Stomach Content Without the Stomach-Tube.**—Friedrich's method of testing conditions in regard to acidity in the stomach by means of a swallowed medicated thread, was described in THE JOURNAL, Sept. 14, 1913, p. 911. He here states that time has confirmed the simplicity and reliability of the method, and has shown further that it is possible by this means to detect the presence of catarrh of the stomach by the irregular staining of the thread. When merely the tip of the thread is stained, this indicates excessive motor functioning, as it shows that there is but little content left in the organ. Irregularity in the staining shows that the stomach contents have not been thoroughly mixed, or else that the stomach contents are mixed with mucus.

81 *Possible Dangers of Mercurial Treatment. (Die Gefahren der Quecksilberkuren und ihre Verhütung.) W. Wolffenstein.

**70. The Rat Flea in Transmission of Plague.**—Kitasato confirms the efficacy of the method of collecting rat fleas by turning guinea-pigs loose in the infected buildings. At Kobe 3,376 guinea-pigs were thus turned loose for twenty-four hours in 774 houses, warehouses, ships, etc., in a period of seventeen months after the small epidemic of plague there in 1909. He emphasizes the importance of the rat fleas in the transmission of plague and the advantages of this method of detecting infection of the fleas. The findings were particularly instructive in forty-two houses which had been supposedly thoroughly disinfected after cases of plague. In eleven of forty-two houses of this kind the guinea-pigs collected infected fleas, showing that the disinfection had not been complete. In thirty-six other houses all the rats had been exterminated and the buildings made absolutely rat-proof; 122 guinea-pigs were turned loose in these houses, but only one flea was found and this showed no signs of infection. Building the rats out is thus shown to be the most effectual means of rooting out the plague.

**76. Recurrence of Eclampsia.**—Holste's patient was an otherwise healthy woman who developed eclampsia near term at her second pregnancy, at the seventh month of the second, at the fourth month of the third pregnancy and just before delivery at the fourth. During the last pregnancy the urine was examined repeatedly for albumin, always with negative results, and she seemed in perfect health. Then the eclampsia developed, extremely severe, but it gradually subsided after the fifty-first convulsion. No influence on the convulsions was noted from the forced delivery but they gradually subsided the following day. With the first eclampsia the convulsions ceased after forced delivery. The second time Stroganoff's prophylactic method was applied with perfect success. At the third appearance of the eclampsia this treatment failed completely, and only forced delivery brought a turn for the better. The fourth attack persisted unmodified by the Stroganoff method and also by forced delivery. The patient succumbed to pneumonia after the subsidence of the eclampsia. Nothing was found to explain the peculiar features of this case; no signs of chronic inflammation of any organ.

**81. Possible Dangers of Mercurial Treatment.**—Wolffenstein has found records in the literature since 1883, of 108 fatalities from the use of mercury. In only one case had the mercury been given by the mouth—fatal intoxication from five pills of 0.06 gm. mercury each. One fatality followed inhalation of the mercury by Welander's sack method. Nine deaths are credited to mercurial oil *(Merkuriolöl)* and ten to mercuric salicylate; in one of the latter group there must have been an absolute idiosyncrasy, as a single injection of 0.05 gm. proved fatal. Seven fatalities are recorded from injection of the soluble preparations and seventy-eight from the insoluble. No less than thirty-one of the fatalities occurred with grey oil, and nineteen with inunctions. He emphasizes the importance of examining the urine before starting a course of mercurial treatment, and repeating the examination *once a week* at least during the course. The various forms in which mercurial intoxication can be manifested are discussed and a case of gangrene of the vagina from this cause is reported, the third on record. The mercury had been given subcutaneously, the salicylate and calomel in moderate doses to a low total. The patient was a young woman with the secondary phase of syphilis; stomatitis developed and the entire walls of the vagina sloughed off, with *fever, but final recovery*. Wechselmann has recently suggested that possibly some of the mishaps attributed to salvarsan were in reality the work of the mercury given with or before it.

84. **Rabies.**—Koch concludes his review of the fifteen years of work of the rabies department of the institute for infectious diseases at Berlin with the statement that possibly potassium iodid might be useful in prophylaxis and treatment of rabies, as it is in syphilis. He refers especially to the cases in which the virus has lurked silently in the body for weeks, months or years, and finally rouses to bring on the rabies in a pronounced form. Nothing is known *that will neutralize* the rabies virus, but he thinks that potassium iodid may influence the tissues of the central nervous system so that they will no longer have an affinity for the virus. This is the explanation, he is *convinced*, of the efficacy of potassium iodid in syphilis; it modifies the tissues that have become pathologic under the influence of the spirochetes and thus renders the medium unfavorable for their growth. Both theory and practice sustain the wisdom of giving potassium *iodid in* rabies, and he has been applying it in this way for nine months as adjuvant to the ordinary inoculation treatment of rabies. Every person taking the Pasteur treatment is given a tablespoonful or dessertspoonful of a 4 to 200 solution of potassium iodid, and thus takes three or four bottles during the course. Therapeutic experience with potassium iodid in actinomycosis, etc., justifies its use in this way. In three cases of abortive rabies all the symptoms rapidly subsided under *it, contrary* to what is usually observed in such cases. A course of potassium iodid after the Pasteur treatment and again during the year might also have a tranquillizing effect on persons who have been bitten by an animal. He warns in regard to the influence of a trauma, overfatigue, emotional stress or abuse of alcohol in rousing the slumbering virus to bring on the disease; it is *now* established beyond question that the virus *can* be present in the nerve tissue without causing any manifestations until something occurs to arouse it to malignant action.

85. **Serodiagnosis in Mental Disease.**—Bundschuh and Roemer applied Abderhalden's technic *to nine* healthy persons, to nine with *manic-depressive* insanity, forty-one with dementia praecox, thirteen with progressive paralysis. Their serum was tested for digestion of brain cortex tissue, thyroid, kidney and ovary or testicle tissue. The results confirmed the specific nature of the ferments elaborated in these various conditions; constantly negative *in* the controls, serum from the dementia cases digested cortex tissue in thirty-five, sexual glands in thirty-four, and thyroid in fourteen cases. The thirteen with progressive paralysis all gave a negative response to thyroid tissue and ten to testicle tissue, but the response was positive with cortex tissue in eleven, *to* testicle tissue in *ten, to both in two, and to* cortex tissue in two. His findings thus testify to the specific character of the defensive ferments elaborated in these forms of mental disease.

87. **Tubercle Bacilli in Lupus Lesions.**—Stern states that he found tubercle bacilli virulent for animals in the discharge from ulcerating lupus on the face in eleven of sixteen patients examined, *namely, in 68 per cent.* He suggests the danger of contagion of others from such persons and the necessity for prophylactic measures.

88. **Zone of Degeneration of the Liver in Pregnancy.**—Heinrichsdorff found necrosis in the center and in the middle zone of the liver in a woman who died the third day after induction of *premature delivery on account* of contracted pelvis. The aspect of the liver seemed normal; only when the liver was opened was the zone of necrosis discovered. The pregnancy had been *apparently normal.*

89. **Latent Erysipelas.**—Berger's patient suddenly developed *intensely itching follicular eczema* over the scalp, face, chest, neck and forearms; it spread the next day but then became stationary. The fifth day the picture changed to that of unmistakable erysipelas *which ran the usual course* and the eczema subsided with it. He declares that the eczema was secondary to the primary erysipelas which had developed in the depths but did not come to the surface until the fifth day. In a second case the eczema developed in the same abrupt manner, but the third day jaundice and other signs of catarrhal icterus developed. *In this case the eczema* was likewise of toxic origin, the first manifestation of the biliary *affection,* and it kept up until conditions righted themselves *in the bile* apparatus (*nine days*).

102 Simple Practical Means for Artificial Respiration to Prevent Danger of Open Pneumothorax. Gelinsky.

94. **Circumscribed Tuberculous Lesions in Long Bones.**—Sixty illustrations accompany the text of Oberst's *article* which gives a general review of the subject, besides presenting his own experience. Each *location* is described on the basis of a few typical cases, with the clinical *picture* presented. In the *great majority* of cases the process starts in the metaphysis, only in the rarest instances in the shaft proper.

96. **Empyema.**—Hirano states that of the 118 patients with empyema given operative treatment at Ise, Japan, since 1900, ninety-three were children. Healing was not complete in adults under six months but the children healed up much faster. Twelve adults died and only eight were permanently cured, but 72 per cent. of the children were cured; 14 per cent. died. The outcome is not known in five other adults and in twelve of the children.

98. **Horse Serum to Enhance Resisting Power of Peritoneum.**—Hirano thinks that injection of horse serum may prove a valuable adjuvant in warding off or curing postoperative peritonitis and in peritonitis from any cause. He applied it in thirty-four cases and was amazed at the rapidity with which already installed peritonitis subsided after intramuscular injection of adults with 40 c.c. sterile horse-serum, children 20 c.c. No effect was apparent in a few cases.

99. **Operative Treatment of Ascites.**—Schwarzmann reports the outcome in fourteen cases of ascites in which operative treatment has been applied since 1906. The data presented emphasize the importance of excluding tuberculous peritonitis and cancer before doing any operation for ascites. Otherwise serious complications may follow. Incipient cirrhosis of the liver is the most promising field for operative treatment. For differential diagnosis the most important elements of the clinical picture are the preascites edema, frequent finding of blood in the stools, initial hematemesis, enlargement of the spleen and general symptoms. By heeding the above symptoms it may be possible to diagnose cirrhosis of the liver in an early phase so that prompt operative treatment may put an end permanently to the tendency to ascites.

111 Study of Influence of Carbonated Baths on the Circulation. Wybauw.

103. **Forced Feeding and Diet in Treatment of Obesity.**—Glaessner emphasies that when there is undernourishment the glycogen disappears first from the liver, muscles and organ cells, then the fat disappears from the cells, mostly from the subcutaneous tissue, muscles and glands. The proportion of loss is for fat, about 95 per cent.; muscles, lymph-nodes and blood, 40 or 50 per cent.; bone, 10 or 15 per cent. The lost albumin cannot be replaced by merely feeding albumin. The patient must have an appetite for his food and consequently change of air and scene, exercise in a pleasurable form, sports, and the preparation and seasoning of the food in an appetizing way are extremely important factors in forced feeding. Sometimes a complete change of diet, as change to an Italian menu, for example, or to sea foods, will answer the purpose. He does not approve of drugs, but advocates hydrochloric acid at need, "although not in the homeopathic doses generally employed." Condurango is also useful and arsenic, as the latter promotes metabolism of albumin.

Von Noorden estimates the normal weight by multiplying the height (in centimeters) by 480 gm. for the maximal and by 430 gm. for the minimal weight. Others estimate it by multiplying the height in centimeters above 100, by 1,000 gm. Oeder measures the distance between the top of the head and the symphysis, multiplies by 2, deducts 100, and multiplies the remainder by 1,000 gm. The undernourished should take about one-fifth more calories than the average for their weight. As a rule it may be said that the diet should include equal proportions of fat and protein with twice this proportion in carbohydrates. Glaessner says of the artificial foods on the market that there is nothing in the world so worthless that it may not be praised to the skies some day as an artificial food, adding that all the albumin-casein-lecithin preparations on the market can be tranquilly dispensed with in feeding the undernourished. He adds that it is disheartening to witness how medical men are willing to promote this advertising of artificial foods by throwing the mantle of science over them. These artificial foods are absolutely unfitted to take the place of foodstuffs; they are not only defectively utilized and merely load down the intestinal tract, but they lack that prime essential in diet, an appeal to the appetite. We can never emphasize strongly enough, he reiterates, the importance of comfort at meals and of appetizing preparation of the food.

In treatment of obesity, extremes should be avoided. Moderate amounts of albumin, carbohydrates of vegetable origin not readily digested, and small amounts of fat should be the basis for the diet, with saccharin instead of sugar. The water-supply need not be reduced. A tablespoonful of oil before meals aids in reducing gastro-intestinal secretion and thus retards digestion while it dulls the appetite. He advocates an occasional day of actual fasting. Physical exercise for the obese is far subordinate in importance to dieting. The restrictions in diet must generally be kept up throughout life. A course of strict dieting to reduce rapidly the obesity is by no means an indifferent matter; it makes great demands on the body as a whole and it is infinitely safer to regulate the habits so as to ward off the return of the obesity.

104. **Reinfection with Diphtheria.**—Reiche states that the records of the Hamburg hospital show 394 cases of diphtheria in the last seven years, in which there had been a preceding attack of the same disease in previous years. In the last two years, of the 4,761 diphtheria patients, 5.8 per cent. were known to have had a previous attack; the largest proportion, 10.9 and 15.8 per cent., were in young adults up to 25, and in adults between 25 and 50. In an additional 1.6 per cent., the second attack of diphtheria was evidently merely a relapse. The data presented confirm the absence of any immunization by a single attack of diphtheria. There were more cases of diphtheria at Hamburg in 1911 than at any time since 1895; 573 of the 4,761 cases in the last two years terminated fatally.

108. **Psychic Heart Murmurs.**—Bensch is convinced that heart murmurs are sometimes the effect exclusively of emotional or psychic influences. He reports twenty-four cases of the kind observed during a recent three months; the murmurs varied from time to time, alternating with normal findings. Vaquez calls them "office-examination murmurs," *souffles de consultation*. Bensch emphasizes as the special features of this group of murmurs their frequency; the exclusive location of the maximal sound in the second left interspace, close to the sternum, and only during systole—he never encountered them at any other point or during diastole; the changeability of the character of the murmur, the varying intensity of the murmur during the examination, during change of position or exercise, increasing in some and declining in others; loudest during deep breathing, and encountered in the delicate and pale and also in robust individuals. These murmurs in certain cases have led to far-reaching mistakes in diagnosis and in the making out of medical certificates, and he warns all to be on their guard with such phenomena in the left interspace. He reviews in conclusion the literature on the subject, although his latest citation from American sources dates from 1889.

110. **Contagiousness of Infectious Diseases.**—Szontagh relates that a child was visiting in a family where measles broke out a few days after her return home. He asked the child's mother to take her temperature systematically as there was every reason to suppose that she had been infected. This was done regularly and the eleventh day the temperature was found slightly above normal, although the child felt perfectly well and had not a trace of nose or throat trouble. The child was at once completely isolated and the measles ran its usual course. Eleven days later the child's four brothers all developed measles. Szontagh says that the child could have

infected her brothers only at the moment when the disease began, that is, when the temperature began to go up. The facts in this and similar cases indicate, he thinks, that the contagion must be air-borne and that it must emanate spontaneously from the infected child, which can occur only in the respired air. It leaves the mucous membrane of the air-passages before it shows signs of disease, and penetrates through the sound mucosa of the predisposed receiver. He argues to prove that the organism must be previously sensitized in some way or the virus will not cause the disease. The fact that the period of incubation is about the same for all the eruptive diseases suggests some close connection between them, as also the fact that the causal agent for none of them has yet been discovered. Measles is spread by school infection, while his experience has been that this is not the case with scarlet fever; the incidence of the latter is greatest in August and regularly declines after October. The solution of the problem of the acute infectious diseases lies, he is convinced, in the study of anaphylaxis. Why does a tonsillitis in one individual assume the form of scarlet fever and in another not? It is a well-known fact that an operation, a severe burn, trauma, overexertion or chilling may bring on an attack of scarlet fever. When sore throats are common, scarlet fever occurs more frequently. Another argument in favor of anaphylaxis as a determining factor is the occasional development of measles, for instance, in children apparently absolutely shut off from any source of contagion; he relates a number of instances of this.

121 Legal Aspects of Medical Practice. (Der Arzt in der Rechtsprechung.) P. Kaestner.
122 Pathology of the Omentum. W. Gundermann.

**112. Regeneration of Axis Cylinders in Vitro.**—A summary of Ingebrigtsen's work in this line was given in The Journal, Feb. 22, 1913, p. 627.

**114. Tonsillectomy in Children.**—*Riedel* remarks that he had rather remove the gall-bladder, the appendix or an ovarian tumor, than operate on a small, firmly embedded and friable tonsil. Tonsillectomy under such circumstances is a serious operation and requires general anesthesia. With ordinary, enlarged *tonsils local* anesthesia may suffice even for children, but he has never *attempted* it as he dreads the child's crying. The general anesthesia has to be *profound* for a short interval which, *of course,* is not without its dangers. The blood swallowed during the operation may be vomited afterward and give cause for alarm, as it is supposed to be the *dreaded* "*hemorrhage.*" He has known of the pillars being sutured together *on this* account when there was really no tendency *to hemorrhage.* He has attempted tonsillectomy a few times in acute tonsillitis but *found the* tonsils too soft and friable to be removed. He warns in conclusion that an imperfect *operation* is worse than none. A diseased tonsil must be removed *in toto,* down to a small bit of sound tissue which he always tries to save. He prefers a stout, unbendable, heavy and straight clamp, 22 cm. long and 5 and 13 mm. broad, with three teeth. This leaves his right hand free for the knife.

**115. Threshold Levulose Test of Functional Capacity of the Liver.**—Hohlweg expatiates on the instructive oversight of liver *functioning afforded* by the alimentary levulosuria *induced* by graded doses of levulose *on* an empty stomach, *taken in 300* c.c. of milk. The urine is collected every two hours afterward for six hours. According as the case looks *suspicious, he gives 50, 75* or *100* gm. of the levulose, increasing or lowering the amount by 25 gm., after a two or three-day *interval until* the limit of tolerance is reached. The tolerance for levulose is *reduced proportional to* the injury of the parenchyma of the liver. The "threshold" response is thus a *reliable index of the present* existence and severity of pathologic *changes in the liver. He tested* the *urine* for levulose by *the Seliwanoff* method, *namely,* the addition to the urine of equal *parts* of *25* per cent. hydrochloric acid and a few crystals of resorcin, *first* shaking up the urine with animal charcoal to decolor it. The test is regarded as giving positive findings when, *on brief* boiling, a bright red precipitate is thrown down *which dissolves in alcohol, giving it a* dark red *tint.* The findings in *about* 105 *cases of* various liver affec*tions show that the tolerance* is materially reduced when the *common bile duct is obstructed* with a gall-stone and in cases of catarrhal jaundice; alimentary levulose follows ingestion of even *50 gm.* levulose. With neoplasms, enough functionally capable cells are generally left somewhere in the liver so that the tolerance for levulose is not materially reduced. The findings often throw light on the diagnosis and prognosis, and the simplicity and ease of the test and the fact that it may reveal pathologic conditions in the liver *long after the morbid cause has been apparently eliminated, render the* method very valuable. In one of the cases cited to *illustrate the* workings of the test, a man of 61 had been having *symptoms* for three months suggesting gastric cancer, and he had lost over 33 pounds in weight in six months. No blood could be found in the stools but urobilin was constant in the urine. There was some levulosuria after ingestion of 100 gm. fasting, and this was accepted as evidence that the trouble was cholelithiasis. Complete recovery followed and there has been no further disturbance *during* the six years since. The retrospective diagnosis was acute disturbance in the liver following temporary obstruction of the common bile duct. In another case a woman of 41 had signs of such obstruction but there was no severe pain at *any* time, while the woman had grown very emaciated during the last few months. All this suggested compression *of the bile* duct by a cancer, but intense levulosuria followed ingestion of 75 gm. and later of 50 gm. of levulose. On the basis of this finding, cancer was excluded and the operation disclosed a small gall-stone lodged in the common bile duct and no trace of a neoplasm.

**116. Sugar in the Blood in Chronic Nephritis.**—*Investigation* of eight patients with nephritis indicated that the sugar content of the blood is abnormally high in nephritis *only* when there is retention of sodium chlorid or nitrogen or both. The same causes which induce reabsorption of the sodium chlorid, cause reabsorption of the sugar *normally* eliminated in the urine.

**117. Technic for Determination of Sugar Content of Blood.**—Bang's method requires only two or *three* drops of blood. They are taken directly from *the lobe of the ear on* a piece of *good* blotting paper 16 by 28 mm. The scrap of *paper* is held with forceps, and it is not allowed to soak up *too much* blood. It is then placed in a test-tube. A *second test-tube holding* 5 c.c. of a mixture of 136 c.c. of saturated solution of potassium chlorid, 64 c.c. water, and 0.15 c.c. of a 25 per cent. solution of hydrochloric acid, is heated and *when* it boils it is poured carefully over the blood-paper. In order to have the fluid come in contact with all the blood he holds the tube slanting. When entirely cool, not until *after half an* hour, the fluid is then poured into a third test-tube, and to it are added 5 drops of the Fehling *II reagent* and 2 drops of Fehling I. It is then boiled for half a minute and watched for two minutes. If no oxydul precipitates out in two minutes, the proportion of sugar *in* the blood is below 0.15, that is, it is *within practically* normal range. The amount of oxydul *thrown down* is an index of the percentage of sugar in the blood.

130 Modern Pathologic Anatomy in the Medical Course. H. Albrecht.

**123. Biologic Test for Absorbed Sperma in Female Serum.**—The research reported was done on rabbits. It demonstrated the presence in the serum of the female after cohabitation of a ferment that digested testicle tissue; beforehand the test had constantly elicited a negative response. The ferment reaction persisted positive in the gravid animals up to sixteen days after littering. Waldstein and Ekler say that these findings indicate that the female organism is materially influenced by substances absorbed from the sperma, causing the production of a ferment hitherto strange to the organism. If these findings apply also to human beings, they would explain certain phenomena in the life of a woman which have hitherto been credited only to psychic processes. Possibly the ninhydrin test for the sperma reaction might prove instructive in certain medicolegal circumstances.

**124. The Blood-Pressure and the Cholesterin Content.**—Cantieri's comprehensive research failed to show any direct connection between an abnormally high blood-pressure and the cholesterin content of the blood. With nephritis there is generally an excess of cholesterin in the blood, even in cases with normal or subnormal blood-pressure.

**127. Prognosis in Pulmonary Tuberculosis.**—Weiss remarks that the outcome in tuberculosis depends more on the reaction of the organism to the infection than on the infecting agent, and consequently our efforts to foresee the outcome must be based on what we can learn of these reactions. In the early stages, the production of lymphocytes in the blood runs parallel to the energy of the defense set up against the invading germs. Forms of tuberculosis with slight tendency to lymphocytosis afford the least favorable prognosis. Tuberculous processes in the lungs make exceptional demands on the lymphocytes, as each tubercle becomes enclosed within a wall of lymphatic cells. Lymphocytes are thus withdrawn from the blood-stream to such an extent that the proportion in the blood may drop to 5 per cent.—a bad sign. Diseases which make special demands on the lymphocytes, such as measles in a child and typhoid in an adult, deprive the organism of the protecting lymphocytes and thus open the portals to tuberculosis, or throw down the barriers around a hitherto latent focus. It is possible that the change to negative of the skin tuberculin reaction in measles and in advanced stages of tuberculosis, is due to the special using up of the lymphocytes in these conditions.

Another sign that the defensive powers of the organism are being overwhelmed is the appearance of urochromogen in the urine. This shows that specific toxic substances are being absorbed, and hence it is a bad sign. The test for urochromogen is extremely simple and reliable. Fresh limpid urine is diluted three times in a test-tube with ordinary water, and then half is poured into another tube and 3 drops are added to it of a 1 per thousand solution of potassium permanganate. In the presence of urochromogen, the fluid turns a canary yellow. The appearance of urochromogen in the urine is a sign that a local circumscribed tuberculous process has changed its character and become general, gravely menacing the organism. The urochromogen disappears from the urine when the organism gets the upper hand again; as long as it is found in the urine the prognosis is unfavorable, and it is the graver, the longer the urochromogen reaction has existed. Comparison of the urochromogen reaction and the skin tuberculin test in eighty-four cases showed concordance in sixty-six. In the eighteen cases in which the findings conflicted, the urochromogen proved the better prophet in all but four cases. Phagocytosis in the sputum is of little moment for the prognosis, according to his experience, and he says the same of Much's granula.

### Zentralblatt für Chirurgie, Leipsic

131 *Symmetrical Gangrene of the Feet Among the Soldiers in the Balkan War. (Cholera- und Typhusgangrän.) A. Welcker. (Eigentümliche Fussgangränen aus dem Balkankriege.) L. Dreyer.
132 *Technic for Orchidopexy. A. Schäfer.

**131. Gangrene of the Feet Among the Soldiers in the Balkan War.**—Two articles were recently published in this *Zentralblatt* and one was summarized in THE JOURNAL, May 24, p. 1675, describing gangrene of the feet among men in the Turkish army. Conditions were similar to those after freezing of the feet, but the weather had not been cold enough to freeze. The cases were reported as "frost-bite without frost weather." Welcker takes exception to this explanation, believing that the gangrene was due to other causes. He encountered 115 cases of it among the men in the Bulgarian army during the same period, and in every instance the men had had one or two weeks before a typical attack of cholera or of dysentery or diarrhea. In forty-five other cases the gangrene developed in men who had or had just recovered from typhoid. After the spread of cholera had been arrested, no further cases of gangrene developed except among those with typhoid. At a later period he encountered hundreds of cases of actual freezing of the feet, and conditions in these cases differed materially from the gangrene following acute intestinal disease. Welcker cites some authorities who mention gangrene as a complication of cholera. In his cases the gangrene was generally symmetrical and the exposure and cold undoubtedly contributed to its development. In the second Balkan campaign the cholera occurred during the summer and no cases of gangrene came to his knowledge. Dreyer ascribes the gangrene among the Turkish soldiers to their way of dressing the feet, which impedes the circulation.

**132 Orchidopexy.**—To prevent retraction and pain—which compelled a second operation in a recent case—Schäfer passes a stout silk thread through the lower pole of the testicle and fastens it to the inside of the opposite thigh at such a distance below that it pulls on the spermatic cord and thus stretches it. The testicle when it is drawn down is forced through a slit in the septum so that it lies with the normal testicle and the septum is sutured behind it. In case both testicles have to be brought down, they are crossed over into opposite sides of the scrotum and the silk threads fastening them to the thighs below are also crossed,

133 *Bleeding in the Ovary in Cases of Uterine Myoma. (Uterusmyom und Ovarialblutungen.) K. H. Oehman.
134 * Roentgen Rays Break up Adhesions in Pelvis. (Lösung parametrischer Verwachsungen durch Röntgenstrahlen.) M. Fraenkel.

**133. Bleeding in the Ovaries with Uterine Myomas.**—Oehman has discovered evidences of ovarian hemorrhage in nine cases of uterine myomas. No traces of inflammation were found in the ovaries or tubes in any instance nor signs of vascular anomalies. Ferguson reported last year a case of serious hemorrhage from the ovary after supravaginal amputation for a large myoma; the woman recovered after removal of the ovary, the seat of the hemorrhage. It issued from a ruptured corpus luteum. The ovaries should be inspected with special care in all operations for uterine growths.

**134. Roentgen Rays Break up Adhesions in the Pelvis.**—Fraenkel has been impressed with the way in which parametritic adhesions binding down the uterus were found loosened up on reexamination of patients a few months after a course of Roentgen-ray exposures for some gynecologic affection. These adhesions holding the uterus in backward displacement are often the source of great discomfort or pain, and this action of the Roentgen rays on them is a welcome addition to our armamentarium. He found it marked in 75 per cent. of the patients he has been able to reexamine recently out of his total 500 gynecologic patients given Roentgen-ray exposures. A second operation became necessary for appendicitis on a patient operated a year before for tuberculous peritonitis at which time numerous adhesions were found, too extensive to be all broken up, and no attempt was made to do this. A large abscess in the pelvis later was treated by roentgenotherapy. At the operation on the appendix no trace could be found of the old adhesions; they had all been absorbed. This also occurred in a second case of tuberculous peritonitis. The action on the adhesions was most evident in a case of ovarian cyst. As the anesthesia was not borne well, the operation was interrupted after the cyst had been evacuated. Some smaller cysts followed causing severe disturbances as they pulled on the bladder, etc. Under roentgenotherapy the discomfort and disturbances all ceased, although the cysts had not been reduced in size; evidently the adhesions had been broken up and absorbed leaving the cysts free and movable, and they ceased to be disturbing. A number of similar experiences are cited, including three cases of pleuritic adhesions and two with relics of pneumonia demonstrating the efficacy of the Roentgen rays in promoting the absorption of adhesions. Fraenkel has found no reference in the literature to this property of these rays except Schulz' mention of their efficacy in treatment of cicatricial keloid.

138 *Otitis Media in Infants. F. Strina.

135. **Exophthalmic Goiter.**—Stern gives an interesting review of the experiences to date with the serum of thyroidectomized animals in exophthalmic goiter and relates its successful application, supplemented by a Nauheim course of carbonated baths, in three cases, two very severe. The patients were women of 29 and 51, and the exophthalmic goiter had resisted all other treatment. In the oldest patient a course of baths the year before had been ineffectual, but this year, supplemented by the serotherapy, remarkable improvement was realized. The much dilated left ventricle subsided to normal size in all the cases. The circumference of the neck grew smaller by 1.5, 2 and 2.5 cm. By commencing with small doses it is possible to improve without by-effects.

138. **Otitis Media in Infants.**—Strina states that he found evidences of otitis media in 70.9 per cent. of the infant cadavers at the Venice foundlings' home. In the last ten years the mortality was 15 per cent., and in 152 of the 346 necropsies there was otitis media on one or both sides, the frequency thus being 44.70 per cent. Of this number about 78 per cent. of the infants were less than six months old. He calls attention to the anatomic conditions which permit infection of the ear from the mouth during delivery or later; the eustachian tube is broader, shorter and more horizontal than later in life, and it can readily become infected from matter forced into it in coughing, vomiting, etc. On account of this broad opening the ear trouble drains readily so that the membrane does not perforate as a rule; perforation was found in only four cases. In a few instances the infection was most probably of blood-borne origin. The otitis media was generally the work of ordinary germs, and the children thus affected were usually in poor physical condition. The otitis media was less frequent the older the infants, showing either that the ear trouble had healed or that the parts had become more resistant. The otitis evidently was primary in some cases and swallowed pus from it entailed gastro-intestinal disturbances. In other cases the primary lesion was in the intestines and the vomit containing infectious material led to involvement of the ear, either directly or by way of the blood. This was probably the mechanism likewise with primary lesions in the lungs. A remarkable feature of otitis media in infants, according to his experience, is the absence of involvement of the mastoid and intracranial region. He suggests in conclusion that deafness and deafmutism may be traced in some cases to unsuspected disease of the middle ear soon after birth.

140. **Means to Prevent Incontinence After Operation for Rectal Cancer.**—Zironi reports a case in which he succeeded in retaining the anus intact and without contamination while the rectum was amputated above. The results were excellent, the patient having complete control over the anus without the least tendency to incontinence during the seven months to date. The special field for the technic is in women, but the principle can also be applied to men. He made an incision encircling the anus, cutting down to the cellular tissue, and then ran a stout silk thread around in a purse-string suture and drew it up tight, thus completely closing the anus. The external sphincter muscle was then divided, cutting down to the intestine along the anovulvar rhaphe and into the vagina. The halves of the external sphincter were then drawn aside and the rectum was prepared for the amputation, suturing the intestine above the cancer to the levator ani on each side to prevent undue traction later. The two halves of the external sphincter were then replaced and sutured together and the vagina restored—all of which was done before the rectum was opened. The wound healed in eight days in his case, permitting administration of castor-oil.

156 Case of Neurofibromatosis. (Een geval van de ziekte van von Recklinghausen.) P. H. van Roojen.

152. **Mistakes in Diagnosis of Skeletal Deformities.**—Korteweg expatiates on the erroneous interpretation of certain findings suggesting deformity of the trunk, and cites several

cases to show how difficult it is to avoid mistakes in diagnosis under certain conditions. Among them is the case of a girl with merely a lumbar protrusion of the spine, but as she happened to have backache, spondylitis was assumed and she was kept long in bed and treated on this erroneous assumption. Korteweg has been studying lumbar kyphosis with special care and has reached the conclusion that in many of these cases the curvature is physiologic. When a young girl, for instance, with a very flexible spine is examined sitting up in bed and stooping forward, we receive an impression very different from that of a body lying on a flat surface. Examining in these conditions we may find a regular kyphotic curvature or lumbar lordosis; lordosis may be complicated with kyphotic protrusion of the middle lumbar spinous process. While an ordinary kyphotic curvature does not suggest spondylitic kyphosis, a limited lumbar kyphosis in the middle of a slight lordosis makes the diagnosis more difficult. If the patient happens to complain of backache, the examining physician is liable to be misled to assume an inflammatory origin for the curvature. If patients are examined standing, these mistakes are less likely to occur.

Another class of cases liable to prove misleading are those in which the chest wall bulges along one side of the sternum. If the patient happens to complain of a pain in the region, an abscess or osteosarcoma is at once suspected, when in reality the bulging is merely the protrusion of the sharp angle of the first and second costal cartilages; the angle becomes less pronounced lower down. If there were in fact a sarcoma at this point, the adjoining ribs would be displaced or the sternum would bulge. A retrosternal abscess or growth would not produce such a sharp point.

The clavicles may be asymmetrical, especially at the junction with the sternum, and the chest is not evenly rounded, while slight traces of scoliosis are evident. With this form of scoliosis there is more than ordinary torsion of the vertebrae. Another class of cases liable to be misinterpreted are those in which the region over the spinous processes of the lumbar vertebrae protrudes. This is the result of scoliosis with considerable torsion of the vertebrae. The bulging of the lumbar muscles during examination may simulate fluctuation. The asymmetry from old scoliosis with its many deformities is sometimes ascribed to intercurrent trauma, and made the basis for claims for damages.

164 Hemorrhage from the Uterus in New Born Infants. V. P. Joukovsky. See Abstract 125, page 1855.

159. **Intrapleural Injection of Epinephrin in Treatment of Pleurisy with Effusion.**—Volkova used epinephrin, 1 to 1,000, in six cases of different forms of pleurisy with effusion. No other remedies were given. The doses varied from 1½ divisions of a common 1 gm. hypodermic syringe to 3, and in the last case (a 4-year-old boy) even 5 divisions. The pulse-rate climbed from 98 to 120, or from 120 to 140, but toward evening of the same day the pulse became the same as before the injection. The amount of urine increased. The number of injections varied from one to six and they were given every second or fifth day. The age was from 2 years and 4 months to 10 years. Five patients recovered almost completely and in a short time, in eight or thirty days; only in two cases were any by-effects from the epinephrin noted, in the form of very transient glycosuria. As children bear the treatment well, Volkova strongly recommends it to the attention of pediatrists.

161. **Mild Chronic Nephritis in Children.**—Stavsky reports two cases of Heubner's paedonephritis levis which, as is well known, does not show grave symptoms. Frequently the nephritis is not even suspected, being merely accidentally discovered. In some cases it manifests itself only as anemia, and the children are treated for this alone. If the urine is examined it is found to contain small amounts of albumin (1:1,000 or 1:2,000), some hyaline and granular casts, leukocytes and erythrocytes. The characteristic feature of this form of nephritis is that the albuminuria is constant, being found in both the day and night urine, but the condition of the patients remains stationary. The children are on an average about 6 years old and have passed through scarlet fever at some time. In Stavsky's cases the condition of both patients has remained stationary during the year or more since, and no treatment or lack of treatment has modified conditions in the least. He recommends in such cases not to keep the patient too long in bed, but to allow him to be up and about and lead the usual life except refraining from food that is liable to irritate the kidneys.

The practical importance of discovering the mild chronic nephritis is that it will warn against measures for the anemia, etc., which might injure the diseased kidneys still more. Stavsky even insists that the urine should be examined for albumin before starting a course of arsenic for anemia in a child, the discovery of albuminuria warning against arsenical medication. He suggests that this mild chronic nephritis is probably more frequent than supposed to date; it escapes detection unless the urine happens to be analyzed for any cause. The parents can be reassured that the nephritis although it may drag along for years, yet persists constantly mild according to the clinical experiences on record to date. (Stavsky's article and the preceding literature on the subject form the basis of an article in the *Semaine Médicale*, October 15.)

163. **Diphtheric Stenosis of the Larynx.**—Uspensky reviews 2,760 cases of laryngeal stenosis from diphtheria; intubation or tracheotomy was indicated in 1,436 cases. Diphtheria bacilli were found in 77.6 per cent., and in sixty-eight cases the diagnosis was confirmed by necropsy, while in 135 cases the membrane was expectorated, so that in 84.9 per cent. the diagnosis was confirmed. Of the total patients, 559 or 38.92 per cent. died, while tracheotomy gave a higher mortality. He does not advise too early intubation as in half of his cases the patients got along without it. The mortality rate in an epidemic does not depend on the time of treatment, but rather on the age—the older the children, the less the mortality. It was highest in infants less than a year old. In such young infants intubation is to be preferred; it gave 37.4 per cent. recovery, while only 4.2 per cent. recovered after tracheotomy. Repeated intubation was necessary in 40.8 per cent. during the first hour that followed the extubation; in 91.1 per cent., it was necessary during the first twenty-four hours. Each patient was intubated on an average, 1.96 times. The best time for removal of the tube is the end of the second and beginning of the third day. The intubation shortens the average duration of the disease; in 51.4 per cent., the course was less than two weeks. With primary tracheotomy it was more than three weeks in 61.1 per cent. When intubation for any reason cannot be done, tracheotomy is of great service; otherwise intubation should be preferred, even at the risk of causing a contact ulceration in the air passages. He never had gangrene develop in children above 2 or 3 years of age, and, in these there seemed to be no relation between the duration of the stay of the tube and the gangrene. The mortality of children with membranous croup depends on the involvement of the respiratory organs. Pneumonia developed after primary tracheotomy in 67 per cent.

173 *Serotherapy of Epilepsy. A. G. Gaspar.

168. **Benzol in Leukemia.**—Fossati's patient was a young woman with severe splenomedullary leukemia, not modified by roentgenotherapy. A fatal outcome seemed imminent when a course of benzol treatment was given and prompt improvement followed. The young woman was not able to bear the large doses of benzol that have been advocated, so the dosage was only from 20 to 60 drops in capsules, suspending the treatment for a day or so occasionally. The temperature returned to normal and by the end of two months the general condition was better than it had been since the first symptoms had been observed a year before. The blood-count at various dates is tabulated showing the increase in the reds and the drop in the whites from 360,000 to 56,000 in three months, the hemoglobin increasing from 35 to 50 per cent.

170. **Extra-Uterine Pregnancy.**—Chiossone reviews the experiences with extra-uterine pregnancy during 1912, in the women's departments of the ten hospitals of Buenos Aires. There were only four deaths among the 105 cases, and in the fatal cases the women were already infected or exsanguinated. He comments on the variability of the symptoms observed and urges that before any abdominal affection in a woman in the child-bearing age is diagnosed, it is necessary to exclude extra-uterine pregnancy. A doughy resistance in the pouch of Douglas is suggestive of a tubal pregnancy, but about the only positive sign of an extra-uterine pregnancy is the expulsion from the uterus of decidual membrane. An important element in differentiation is a history of some gynecologic affection; the ovum scarcely ever locates outside of the uterus unless there is a predisposition from preceding pathologic changes for the abnormal embedding. Increasing hemorrhage always demands an operation, but if the hemorrhage seems to have stopped he leaves the case to Nature, ready to interfere at need. He gives the details of ten cases; in one the woman passed through two extra-uterine pregnancies. In conclusion he warns that it may be necessary in some cases to be wary in stating the diagnosis of extra-uterine pregnancy, as social and legal questions may be involved. There is always the possibility that the accumulation of blood may come from an ovarian or other tumor in the absence of pregnancy.

171. **Dermoid Cyst Interfering with Delivery.**—In the case described the cyst was punctured and the contents withdrawn through a wide trocar after which the child was safely delivered. Three months later the cyst was removed by the vagina; it weighed then 100 gm. Analysis of the literature on the subject shows that removal by laparotomy of a cyst interfering with delivery has frequently entailed serious complications for mother or child or both, while vaginal removal is simple and harmless if preceded by puncture and evacuation of the contents of the cyst. This permits natural delivery and normal puerperium. The cases on record are summarized to show the advantages of this technic over the abdominal technic or colpotomy.

172. **Necessity for School Dental Clinics.**—Patrone's article was read at the recent international congress for school hygiene held in Buffalo. He reiterates anew the seriousness of dental caries for the development of the child, the importance of prophylaxis, and the necessity for those realizing this importance to organize, formulate and direct the propaganda for hygiene of the mouth and teeth among schoolchildren as a matter of vital importance for the public health.

173. **Serotherapy of Epilepsy.**—Gaspar gives no details but speaks in general terms of the conception of epilepsy as a toxemia, evidenced by the toxicity of the cerebrospinal fluid for animals, and by the efficacy of reinjection of the patient's own cerebrospinal fluid or fluid from other epileptics. The fluid is injected subcutaneously or into a muscle once a week, the amount not over 10 c.c. He queries whether the undeniable unmistakable improvement and even cures realized by this serotherapy can be explained by assuming the existence of antibodies in the fluid.

175 *The Sugar in the Blood. (Blodsukkerundersøgelser under normal og nogle patologiske Forhold.) I. Bing and B. Jakobsen.

176. **The Sugar in the Blood.**—Bing and Jakobsen report the results of estimation of the sugar content of the blood in sixteen normal persons, in thirteen with kidney disease, in seven with stomach or pancreas disease, in five with merely nervous disturbances, in seven with diabetes, and in six suspected of diabetes. The estimation was made by means of Bang's technic which they regard as an improved method for the purpose on account of its simplicity, rapidity and the fact that only a drop or two of blood is required for the test. (It is described in abstract 117 above.) The normal range was from 0.06 to 0.12 per cent., the average 0.1. The test was applied always at the same hour, 8 a. m. fasting. In a series of tests on a similar group of ten healthy persons given 100 gm. sugar in a cup of tea, the sugar content of the blood was found materially increased one hour afterward, but by the second hour the proportion had dropped back to the previous figure. This shows the importance of making the tests always under the same conditions and of being on the lookout for the briefly transient alimentary hyperglycemia. In two other cases, men of 55 and 60 had been taking very large amounts of sugar systematically on account of a chronic heart disease, hoping thus to improve the nourishment of the heart. Even with these doses of 250 gm. of sugar and above, the sugar content of the blood kept within normal range. In kidney disease the sugar content was a little above normal in a few of the thirteen patients tested, but it generally dropped to normal during the stay in the hospital and there was no abnormal alimentary hyperglycemia. The findings showed further that there is no constant relation between the sugar content and the blood-pressure; each may run an independent course. No excess of sugar in the blood was found in the cases of stomach or thyroid affections or neurasthenia, but there was a slight tendency to hyperglycemia in a case of acute pancreatitis and of cancer involving the pancreas. With polycythemia there was hyperglycemia, on account evidently of the large proportion of reducing substance in the blood corpuscles. With diabetes, the sugar content was abnormally high both fasting and after meals, but the hyperglycemia and the glycosuria did not run parallel; the latter may exist with normal sugar content in the blood. This emphasizes the kidney element in diabetes. In seven typical cases of diabetes, the sugar content ranged from 0 071 to 0.146 per cent. in one patient aged 44 in the course of a month. The range in the total seven was from 0.071 to 0.265 per cent. The great practical importance of the research reported lies in the fact that by examining the blood for sugar in dubious cases of diabetes or when the condition has improved under treatment, we are able by estimation of the sugar content to determine whether the diabetes has actually been conquered or whether it is liable to flare up again on any indiscretion. In such cases the casual and occasional appearance of glycosuria with normal sugar content in the blood may be accepted as a comparatively trivial phenomenon, not fraught with serious consequences.

# THE PRODUCTION OF ULCER OF THE STOMACH BY INJECTION OF STREPTOCOCCI *

E. C. ROSENOW, M.D.
CHICAGO

Hemorrhages, superficial erosions and definite ulceration of the mucous membrane of the stomach and duodenum occur not infrequently during severe infections in man and in experimentally infected or otherwise severely intoxicated animals. In some of these instances there can be no question but that infection in some instances plays a rôle in the etiology of ulcer.[1] Ulcer also has been produced experimentally by injecting bacteria into the gastric artery. The association of mouth and tonsillar infections with ulcer of the stomach has been emphasized. It is said that ulcer of the stomach is more common in regions in which throat infections are particularly prevalent. Clinicians have observed aggravation of symptoms in ulcer of the stomach or duodenum following sore throat. Experimental proof, however, showing that certain bacteria may have a special affinity for the stomach mucous membrane, producing a localized infection, and hence may play a rôle in the causation of the common acute and chronic peptic ulcer in man where the usual symptoms of infection are slight or wholly absent has not been brought forward. In a short note on the etiology of rheumatism[2] I pointed out that ulcer of the stomach followed not infrequently intravenous injections of organisms isolated from rheumatism, especially after animal passage; of laboratory strains of streptococci after they had attained a certain grade of virulence from animal passage, and of emulsions of tonsils which were removed chiefly during convalescence in cases of rheumatic arthritis. I wish here to report experiments along this line.

Ulcer of the stomach or duodenum, or both, have been produced by intravenous injection of certain streptococci in eighteen rabbits, six dogs and in one monkey. The ulcers are usually single, although at times two or more may be present. The primary hemorrhages and later the ulcers are small and deep. The base of the ulcer is usually clean or filled with a brownish blood-clot. There may or may not be a localized peritonitis. Perforation into surrounding adhesions occurred in two dogs and in the monkey. The tendency to bleeding in these ulcers is great. Two dogs died of an acute hemorrhage, while another was bleeding when chloroformed. The rabbits often showed considerable blood in the intestines, although death could not be attributed definitely to hemorrhage in any. Both punctate hemorrhages and ulcers have been found most frequently in the pyloric end of the stomach, then in the fundus, and least often in the duodenum. It should be pointed out that the hemorrhages and ulcers in these experiments are small and sharply circumscribed, and there is not the tendency to digestion and sloughing of mucous membrane—in contradistinction to hemorrhages and erosions—observed after anaphylactic shock, after overwhelming bacteriemic infections and other severe intoxications. In most of the rabbits and in some of the dogs which showed ulcers there was also arthritis, in some myositis and the picture of an "ascending" nephritis. Cholecystitis, with beginning formation of gall-stones, and appendicitis have also been found.

It must not be supposed that the ulcers are accidental, because they occur, commonly, only when streptococci of a certain grade of virulence are injected. To illustrate: Strain 319, originally a pneumococcus which was isolated from the blood in lobar pneumonia six years ago, and which had lost its virulence, resembling now a streptococcus, was passed through nineteen rabbits. The first thirteen passages (intravenous injections) failed to show ulcer in any, while the next six passages showed ulcer of stomach three times. Strain R51A, originally a pneumococcus isolated from the blood in pneumonia nearly eleven years ago but recently transformed into a hemolytic streptococcus, was passed successively through twenty rabbits. In the first fifteen animals ulcer was not found, while the next five passages showed ulcer of stomach twice. The strains from rheumatism before animal passage produced ulcer in two out of sixteen animals; after from two to five passages ulcer was produced in seven out of eighteen rabbits, while after from five to ten passages again only once in eight animals injected. When the virulence is very low ulcer occurs very rarely; when virulence is of a certain grade, slightly higher than that of the streptococcus from rheumatism, it occurs commonly; but when the virulence becomes still higher ulceration of the mucous membrane is again rare. It is practically impossible to produce this type of ulcer of the stomach with *Streptococcus viridans* as isolated from the blood in endocarditis or with highly virulent hemolytic streptococci or pneumococci.

The grade of virulence of the organisms when ulcer is obtained, commonly, is such that they disappear from the general circulation and the uninjured tissues. This fact afforded opportunity to study the exact relation of the organisms injected to the small areas of hemorrhage in the mucous membrane and to the ulcers. The areas of hemorrhage and ulcers were cut out, in four animals, together with corresponding pieces of the healthy stomach wall, washed thoroughly in repeated changes of sodium chlorid solution, crushed in a mortar, suspended in sodium chlorid solution and a series of blood-agar plates made. Cultures from the blood were also made. In one animal which died twenty-four hours after a third injection the blood still contained a moderate number of streptococci. Streptococci were recovered from the healthy, the hemorrhagic and the ulcerated area. The healthy area showed five, the hemorrhagic area eighty-two, the ulcerated area sixty colonies. Saprophytic bacilli and colon bacillus were present in small numbers in each. In the other three in which the blood was sterile the cultures from the healthy portion showed no streptococci in any, while the ulcerated or hemorrhagic areas yielded streptococci in varying numbers in each instance. Smears and blood-agar plate cultures from the base in other acute and in more chronic ulcers showed streptococci resembling those injected.

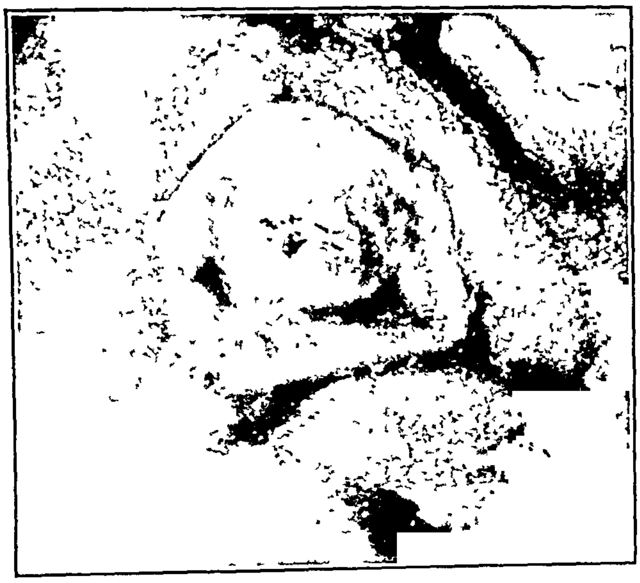

Fig. 1.—Necrosis with beginning ulceration of mucous membrane of stomach in a dog injected intravenously thirteen days previously with a streptococcus of low virulence; from photograph × 5.

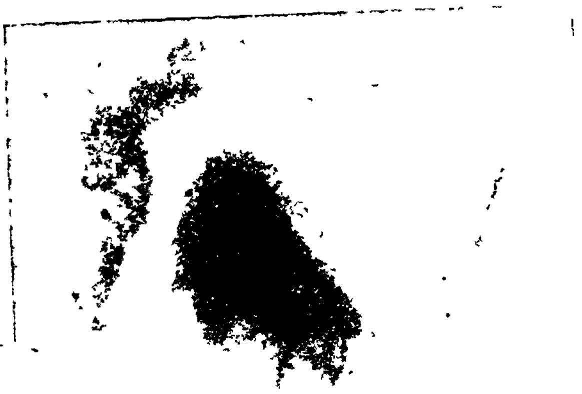

Fig. 2.—Deep, round ulcer at pyloric end of stomach of dog injected intravenously one month previously with a strain from rheumatism after ten animal passages; from photograph × 5.

MICROSCOPIC ANATOMY

The areas of hemorrhage which occur within twenty-four hours after injection usually extend through the whole thickness of the mucous membrane. The blood escapes from the capillaries in the acini and not from a larger vessel in the submucosa. It is most marked and extends over a wider area as the inner surface is reached. Leukocytic infiltration is already present in twenty-four hours, while at the end of forty-eight hours when ulceration has begun it is often quite marked and later is found to extend into the submucosa and muscular coat. The reaction indicating an infection in some ulcers largely disappears after the ulcer has existed for a long time. This is especially so in those ulcers in which invasion of the underlying structures is absent or slight.

The ulceration begins on the surface and rapidly extends to the submucosa. The tendency to invade the submucous and muscular coat is marked and was present in every instance when marked hemorrhage was observed (Fig. 5). The margins are usually abrupt, often undermined and infiltrated. The early picture is well illustrated in Figure 6 and the later appearance in Figure 5. In the former ulceration has not yet extended through the entire thickness of the mucous membrane, whereas in the latter the round-cell infiltration and ulceration have extended well into the muscular coat. In the latter there is a layer of leukocytic infiltration invading the normal tissue. Inside of this the cells show granular degeneration, the nuclei become fragmented as they lose their affinity for stains until finally a more or less homogeneous necrotic layer lines the ulcer. In horizontal sections the ducts along the margin of the ulcer frequently are found to contain leukocytes and red blood-corpuscles. Under high power the early infiltration in the wall of the ulcer is found to be made up chiefly of leukocytes and red blood-corpuscles; later lymphocytes and large mononuclear cells predominate. Here, also, what appear to be plasma cells are found in small numbers. Giant cells have not been observed. The chief cells disintegrate earlier than the parietal cells, giving the erroneous impression that the latter have actively multiplied. The connective tissue stroma of the acini is most resistant and can be made out for considerable distance beyond the place where the other cells, including leukocytes, have disappeared.

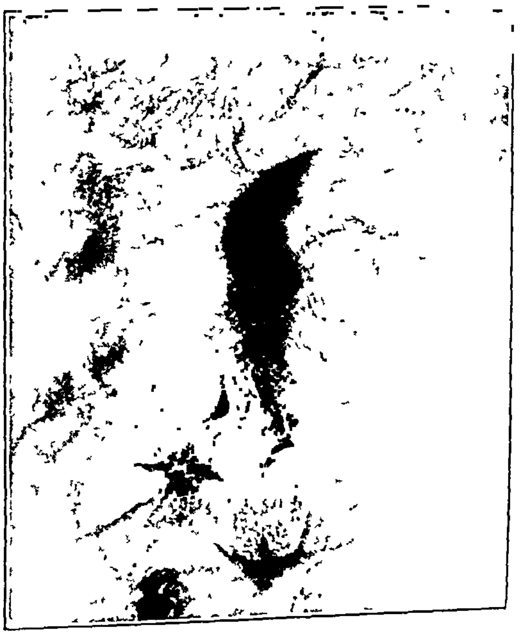

Fig. 3.—Ulcer of stomach in monkey injected intravenously with a strain of streptococcus from rheumatism after it had been converted into the hemolyzing variety and passed through one animal; from photograph × 5.

Thrombosis of adjacent blood-vessels has not been found in the acute ulcers but has been found in veins in two of the more chronic, deep ulcers in dogs. One of these died of acute hemorrhage. The other was chloroformed while bleeding was going on. Sections stained for bacteria by the Gram-Weigert method showed diplococci and short chains in the ulcers, as early as forty-eight hours and as long as twenty-eight days after single injections of streptococci. These were found here repeatedly when the cultures proved their absence in the blood, pelvis of kidney, joints and gall-bladder. Figure 7 shows a moderate number of organisms. They are approximately half way between the free surface of the ulcer and where the cells still stain in a normal way. In this instance the injection of an emulsion from the tonsils was made thirteen days previously (see protocol, Dog 22). The organisms were easy to find. Some areas showed many hundred streptococci in linear arrangement in the connective tissue stroma of the disintegrating acini. Single diplococci were found in the deeper and less disintegrated areas (Fig. 7). The ulcer in one dog which was chloroformed twenty-eight days after a single injection showed fewer diplococci, well down from the free surface of the ulcer. Leukocytic infiltration in this instance had almost entirely disappeared.

It is interesting to note that in all the examinations which were made for bacteria only two Gram-staining bacilli were found and these were on the surface of the ulcerated area. Gram-staining diplococci were found in the thrombus of an adjacent vein in one instance. A painstaking search for similar organisms was made in the normal structures away from the ulcer, but none were found.

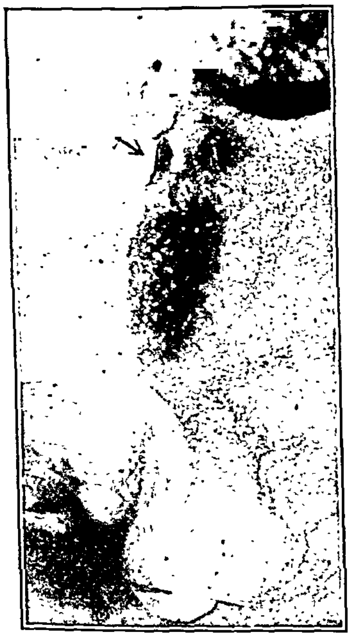

Fig. 4.—Ulcer of duodenum just beyond pyloric ring in rabbit injected intravenously with a streptococcus of low virulence.

## ILLUSTRATIVE PROTOCOLS

The rabbits were fed carrots, hay and oats, the dogs a mixed diet with liberal quantities of meat.

Rabbit 475.—Injected intravenously on May 9, 12, 15 and 19, with the growth from 16 c.c. of ascites-dextrose-broth of Strain 744 from a case of articular and muscular rheumatism. May 19: Lameness in and swelling of right knee-joint; very ill. May 22: Chloroformed and examined at once. A few lesions in the flat muscle of the groins and shoulder. Myocardium, gray and flabby, shows a few whitish areas in papillary muscles. Clear fluid in pericardial sac. Fluid from three joints turbid, containing leukocytes, while that from another joint is clear. The stomach is normal except for the presence of two circumscribed, punched-out ulcers in the pyloric end. The larger is 4 by 2 mm. The base of each is occupied by brownish clotted blood. The margins are elevated, undermined and infiltrated (Figs. 4 and 6). Duodenum is normal. The contents of the large bowel are dark brown in color and give a strong Weber test for blood. The kidneys show no changes except a few whitish elongated areas in the medullary portion. The gall-bladder is filled and the ducts are distended with a slightly greenish viscid mucus containing large masses of pus. Pressure on the gall-bladder, after the plug of pus and concretions in the ampulla of Vater is removed, easily expels the contents into the lumen of the intestines. The masses of pus, on washing and disintegration, are found to contain concretions the size of millet-seed which have the consistency of putty. Smears of the pus show many leukocytes and streptococci. The addition of hydrochloric acid to the concretions liberates carbon dioxid. In the wall of the gall-bladder are found three small round whitish areas which seem to involve chiefly the mucous membrane. Over the largest of these at the fundus there is an adhesion to the omentum. The lungs, liver, brain, intestines, appendix and adrenals show no changes. The spleen is not enlarged. Cultures from the blood, peritoneum, pericardium, pelvis of kidney and two joints prove sterile. The most turbid joint fluid gives a few and the bile a large number of slightly hemolytic streptococci in pure culture, while the base of one of the ulcers in the stomach gives a few of these and saprophytes. One of the concretions, thoroughly washed in sodium chlorid solution, then crushed and used for plate cultures gives a pure culture of streptococci.

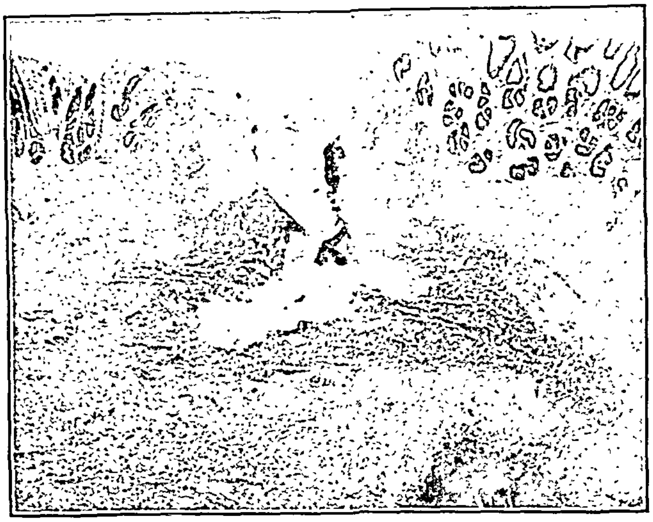

Fig. 5.—Section of ulcer of stomach in Dog 22; died from hemorrhage (see protocol). Note the leukocytic infiltration in the submucosa at base of ulcer, the great depth and extension of the ulcer beyond the mucous membrane. Hematoxylin and eosin; from photograph × 35.

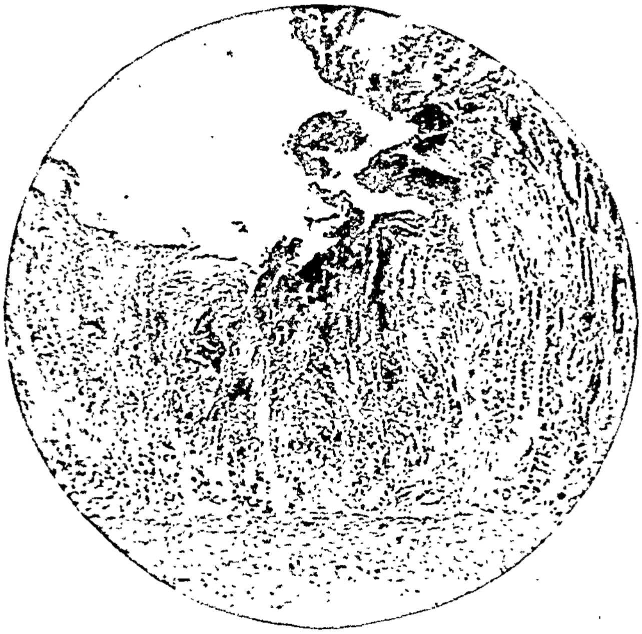

Fig. 6.—Section of ulcer of stomach in Rabbit 475. Note the hemorrhagic base (dark material), the tendency to undermining of margin, and the cellular infiltration at base. Hematoxylin and eosin; from photograph × 90.

Dog 22.—Small young dog. Injected March 18, 1913, with 5 c.c. of an emulsion of a tonsil, removed from a patient following an attack of tonsillitis and articular rheumatism. March 19: Lame in left front leg. Smears from left front wrist-joint show leukocytes and Gram-positive diplococci. Cultures yield green colonies only. March 21: Cultures from blood show a few hemolytic colonies only. Lameness still present, wrist-joint swollen. March 24: Lameness absent, wrist-joint no longer swollen, has lost in weight, lies quietly in corner, drinks water but eats little. Cultures from blood negative. March 29: Still quite well but has grown thin, does not eat. March 30: Dead. Muscles, mucous membrane and other tissues very pale; hemoglobin 12 per cent. Smears from the blood show a few reds and leukocytes. Recent, probably agonal, intussusception at ileocecal valve, easily reduced. Large quantity of partially digested blood in bowel above intussusception, nothing below. Stomach normal except for a deep ulcer in the pyloric ring, measuring 7 by 4 mm., long diameter vertical. The ulcer is filled with a brownish blood-clot, the margins infiltrated and grayish red (Fig. 5). The peritoneum is thickened directly over the ulcer and there is adhesion to the omentum. Heart, kidneys, liver, spleen, adrenals and brain show no changes. Cultures from blood, pericardium, joints, pelvis of kidney and bile sterile, but a blood-plate from material at the base of the ulcer after removing the blood-clot gives an almost pure culture of streptococci (Fig. 7).

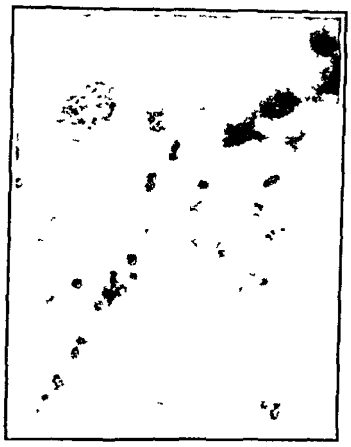

Fig. 7.—Streptococci in the disintegrating connective tissue in the margin of the ulcer shown in Figure 5; × 1200.

Dog 21.—Small, brown and white. Injected *intravenously* March 13, with the growth from 300 c.c. of ascites-dextrose-broth of Strain 734, ten animal passages after isolation from a case of rheumatism. Dyspnea, vomiting and great weakness following injection. March 14: Seems fairly well but has developed severe double conjunctivitis; smears from pus contain Gram-staining diplococci. March 15: Blood-agar plates from pus from eyes show almost pure cultures of green colonies resembling those injected. March 18: Seems ill; has lost in weight. Marked tenderness and swelling of right wrist and elbow-joints. Muscles of back and about shoulders seem tender. March 21: Cultures from joints show few green colonies. Seems better but eats very little and continues to lose in weight. Heart action slow and very irregular. Discharging sinus above right wrist. March 23: Cultures from discharging sinus contain chiefly green colonies. April 10: Chloroformed. Mucous membrane and tissues quite pale. Sinus above wrist leads along muscle sheaths. Fluid from elbow-joint turbid; no connection between elbow-joint and the suppuration adjacent to it. Pericardium empty; whitish linear areas in myocardium; endocardium normal except for a nodular thickening in posterior leaflet of tricuspid valve. Localized adhesive pleuritis. Stomach normal. Duodenum shows a rather large, round ulcer, 2.5 cm. from the pyloric ring and measuring 8 mm. in diameter. The margin is thickened and undermined, the base covered with a brownish blood-clot. The omentum is adherent. The contents of the large intestine blackish and gives a strong Weber test for blood. Liver shows moderate fatty degeneration. The kidneys present a number of small whitish areas in cortex. There are a number of whitish streaks in skeletal muscles, most numerous in the muscles about shoulder and in intercostal muscles; none in diaphragm. Several teeth are loose and there is osteomyelitis of lower jaw. Smears from pus around elbow-joint and lower jaw contain large numbers of Gram-staining diplococci. Cultures from blood, pelvis of kidney and pericardial sac sterile, from elbow-joint give a moderate number, from pus of discharging sinus and pus in lower jaw a large number of slightly hemolyzing colonies.

Monkey.—Injected into vein of forearm on March 18 and 20 with the growth from 100 c.c. ascites-dextrose-broth of Strain 734H. Died on April 2 after severe diarrhea. Only the changes in the stomach are given here. The stomach is normal except for three deep ulcers, two near the pyloric end, the other and the largest in the pyloric ring. All have a clean base and are undermined with infiltrated margins. The largest has bridges of mucous membrane over undermined portions (Fig. 3). The omentum is adherent and, on dissection of the adhesions over the largest ulcer, a small perforation of the serous coat is found. Small intestines normal. The mucous membrane of the large intestines is red, the lymph follicles are much swollen and a number show superficial ulceration. The lymph-nodes in the mesentery and about the pyloric end of the stomach are enlarged and hyperemic. Purulent material in one ulcer in the stomach shows saprophytes and colon bacilli only, but from a small piece of the wall of one ulcer thoroughly washed and crushed, there are obtained in addition to a few contaminating organisms fifteen colonies of streptococci, whereas a similar portion of adjacent healthy mucous membrane shows no streptococci.

## SUMMARY

Intravenous injection of streptococci of the proper grade of virulence may be followed by ulcer of stomach and duodenum. The ulceration is due to a localized infection and secondary digestion. The ulcers are usually single and deep with marked tendency to hemorrhage and perforation, and resemble the human gastric ulcer in many respects. When we take into consideration this close resemblance, that injection of streptococci which have grown in tonsils produce the lesions, and that the virulence of the germs when the *affinity* for the stomach is greatest is of such character that a general infection does not occur, it appears altogether reasonable to suppose that in man gastric ulcer may be caused by streptococci also. The supposed relation between infected tonsils or gums and gastric ulcer may be due not to the swallowing of bacteria, as usually supposed, but to the entrance into the blood of streptococci of the proper kind of virulence to produce a local infection in the wall of the stomach. Many other observations might be cited such as associated infections of the gall-bladder and appendix, which suggest that gastric ulcer may be due to streptococci.

122 South Michigan Avenue.

**Then as Now.**—We are prone to surround the past with a kind of mystic glamor. We do not give honor where honor is new, but reserve our panegyrics for times and methods whose inaccessibility denies all chance of refutation. For example, we think the middle ages knew something about toxicology. So they did, but not a tithe of what we vaguely give them credit for. The old apothecary was not a pocket Borgia. Men were asked out to dinner and they sometimes died after it. But *post cibos* is not necessarily *propter cibos*, and one man's meat was not always poison for another. There was not always death in the pot. If we look at a sixteenth-century menu we have a general feeling, not of amazement that men should occasionally die after a banquet, but rather of surprise at the survivors. Then it is probable that modern surgery would have saved some of these moribund postprandialists—that perforation, not poison, ushered them into the *Ewigkeit*. In fact, these terrible toxicologic tales suffer from exaggeration. The morality of the times demanded sudden death in convenient form, and an alleged supply arose. It is much the same as if our day was judged by its patent-medicine advertisements. Reading them, a truthful age would sigh and offer illimitable gold for what we can buy for 1s. 1½d. As a matter of fact, we do not buy them. We know that some men are liars now, but we forget that there were liars in those days.—*Med. Press.*

# MILIARY TUBERCULOSIS OF THE PLACENTA

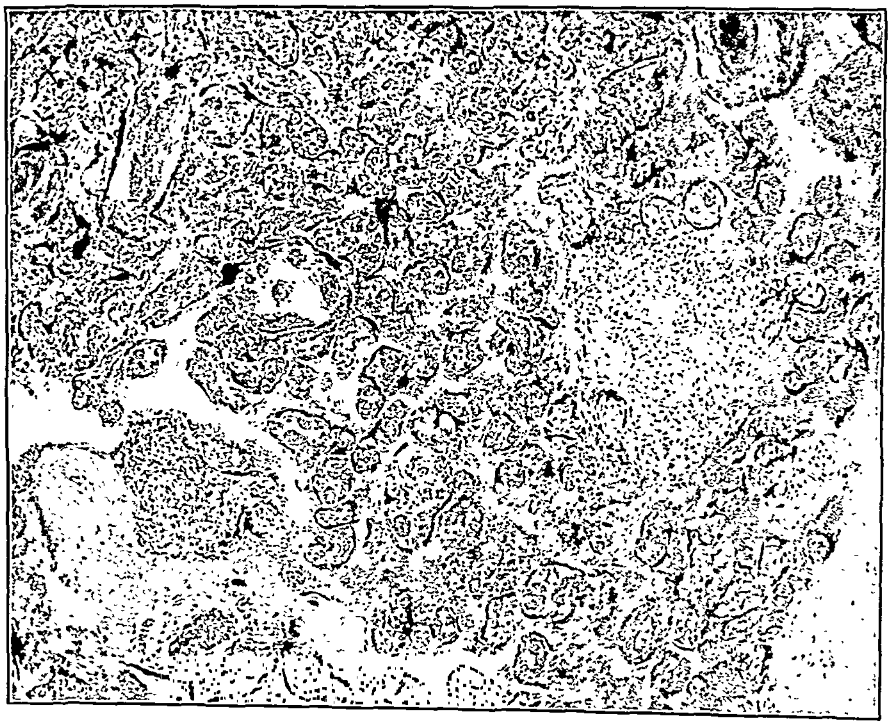
## WITH INCIPIENT PULMONARY TUBERCULOSIS OF THE MOTHER BECOMING LATENT AFTER BIRTH OF CHILD

ALDRED SCOTT WARTHIN, Ph.D., M.D.
Professor of Pathology and Director of the Pathological Laboratory, University of Michigan, Department of Medicine and Surgery
ANN ARBOR, MICH.

The case recorded here is of great importance in that it demonstrates the possibility of the transmission of tubercle bacilli to the fetus from a mother having an unrecognized latent tuberculosis of one apex. In the cases of placental tuberculosis recorded in the literature up to the present time there is no reported instance of such an occurrence; all of the cases of placental tuberculosis are given as occurring in association with advanced pulmonary or acute miliary tuberculosis of the mother. Tubercle bacilli, however, have been demonstrated by the antiformin method in placentas coming from mothers with incipient tuberculosis of the lungs, but no histologic evidences of tuberculosis were found in such placentas, and no congenital transmission of the disease to the offspring has been shown beyond doubt to occur in such cases.

It has been generally assumed that the entrance of tubercle bacilli into the blood-stream and their lodgment in the placental sinuses is a rare event, likely to occur only in pregnant women showing a late stage of pulmonary tuberculosis. If it can be shown that in pregnant women who have incipient pulmonary tuberculosis lesions the bacilli may enter the circulation under the influence of pregnancy and cause a miliary tuberculosis of the placenta or congenital infection of the fetus, the sociologic and eugenic aspects of the transmission of tuberculosis from parent to child become greatly increased in importance. It is generally recognized that the influence of pregnancy on maternal tuberculosis is bad; and observations are only too frequent of the kindling of incipient and latent pulmonary lesions and the exacerbation of more severe processes through this factor. While the majority of writers on tuberculosis concede that pregnancy acts unfavorably on the disease so far as the mother is concerned, practically all unite in minimizing the dangers of congenital transmission to the progeny of such tuberculous mothers, and this in spite of the not slowly accumulating cases of placental tuberculosis. For that reason especially I regard this additional case of placental tuberculosis discovered in my laboratory as of very great importance in throwing more light on the possibility of such a transmission.

All placentas obtained in Dr. Peterson's obstetric clinic in the university hospital are subjected to a routine gross and microscopic study in the pathologic laboratory. During the course of such routine examination, a placenta sent to the laboratory on Oct. 28, 1912, was found by me, on microscopic examination, to contain miliary tubercles in practically every section. Inasmuch as the history of the mother sent with the placenta made no mention of the existence of tuberculosis or the possibility of such disease in her, my interest was at once excited in the case, and it was studied from all possible angles. The history of the mother as given was entirely negative as to tuberculosis, as follows:



Two miliary tubercles from placenta; one, at the right, is healing; at the left is one more recent. epithelioid and situated on the chorionic stem; a latent lesion was in right apex of mother.

Miss A. B., a domestic, aged 20, was admitted to the University Psychopathic Hospital in February, 1912, with "hysteric insanity." At the age of 18 she had measles and scarlet fever and since has been very "nervous." There is no family history of tuberculosis and the patient, so far as she knows, has never been exposed to the disease. When she entered the hospital she gave a rather definite history of gonorrhea. Physical examination in other respects was negative except that she was found to be pregnant and was referred to the maternity ward, where after an apparently normal pregnancy she gave birth to a viable child on October 28. The placenta was tagged with the mother's name as soon as delivered and the course of the specimen is known without chance for error. When the diagnosis of miliary tuberculosis of the placenta was returned the mother was referred to the medical clinic for a thorough examination. The findings again were negative except that at times the pulse-rate was rather rapid (108) and on exertion she had a slight dyspnea.

*Examination* (by Dr. Hewlett Nov. 13, 1912).—Patient was referred for chest examination on account of miliary tubercles having been found in the placenta. Examination of chest shows that the right apex behind shows slight increase in fremitus, beyond the normal difference, slight impairment on percussion and somewhat harsh expiration. There are no râles. No active tuberculosis is found in the lungs, but there is some suspicion of a healed process at the right apex.

*Examination* (by Dr. Schmidt).—Eyelids are slightly puffy; hands are cold and clammy, with slight cyanosis of the finger tips. No enlarged lymph-nodes are found in the neck. The right upper chest expands less than the left. Litten's sign is not seen on either side. The right upper is not so full below the clavicle as is the left upper. Expiration is rather harsh over the right upper in front. The back shows slight impairment over the right upper with slight increase in tactile fremitus, as well as of whispered and spoken voice. Expiration is somewhat increased over the right upper behind. No râles are heard.

*Tuberculin Tests.*—There is a slight reaction to 25 per cent. in ninety-six hours (von Pirquet).

*Subcutaneous Test.*—Two mg. of tuberculin were injected at 10 a. m., November 5; at 2 p. m., November 6, there was slight redness around area of injection, and area was very tender. Highest temperature was 99.2 F. Dec. 7, 1912, patient was given 5 mg. of tuberculin, subcutaneously. On noon of the following day, temperature reached 99.7 F., falling to normal toward evening. The area of injection was red, indurated and tender. No râles were heard.

Roentgenoscopy reveals slight increase of root shadows but no definite sign of tuberculosis.

Medical examination shows a positive *tuberculin test*, a suspicious right apex, but no evidence of active disease.

From these examinations it is evident that the patient has had an incipient tuberculosis of the right apex, now no longer active. It can be inferred that earlier in pregnancy this apical lesion was active for a time, and that bacilli then escaped into the blood-stream and into the interchorionic spaces. This assumption is supported by the character of the placental lesions. In practically every section made of this placenta there were miliary tubercles, in all respects characteristic histologically. The average section contained from four to six tubercles. Very few of these tubercles were recent ones. No absolutely fresh miliary thrombi, such as characterize the early miliary tuberculosis of the placenta, were found. The majority of the tubercles were epithelioid in type with a tendency to healing, as shown by the development of a more mature connective tissue in and about the tubercle, some of the tubercles appearing more fibroid than the connective tissue of the villi. Giant-cells were not frequent. Many of the tubercles showed no caseation or only a slight central caseous change; only a few showed a marked central caseation. Tubercle bacilli could not be found in the epithelioid and healing tubercles, but were demonstrated in small numbers in the caseating tubercles. There is, therefore, no doubt as to the nature of the process. The healing tubercles are easily distinguished from small infarcts by their sharply circumscribed borders and by the fibroblastic proliferation of the villi included in the primary intervillous thrombus to form a compact epithelioid mass. When transition stages from the earliest form of the placental tubercle up to the healing stage are present, as in this material, there is little likelihood that any one who is familiar with the histologic characteristics of placental tubercles would hesitate in immediate recognition of the nature of the process; but if the healing forms alone were present and in small numbers there might be difficulty in such recognition. There are, however, but two things that need to be considered in the differential diagnosis: small localized areas of syphilitic chorionitis and small infarcts showing reparative changes. In the former the syphilitic process involves only the stroma of the villi, and the villi are not fused into a solid fibroblastic or fibroid mass; in the healing infarct the villi may be fused, but there is no fibroblastic formation, or only the slightest, between them.

The healing tubercle, on the other hand, may show outlines of some villi fused into an intervillous epithelioid or fibroblastic proliferation. In this case all stages of tubercles were present, although the majority were in the healing stage, and the presence of tubercle bacilli makes the diagnosis absolutely certain, although the histologic changes are in themselves sufficiently characteristic.

This case, therefore, presents a placental miliary tuberculosis of a low virulence, the majority of the tubercles being in a healing stage. It is very probable, then, that in the earlier months of pregnancy, most likely in the third or fourth month, a latent tubercle in the right apex became active, gave access to the blood of tubercle bacilli that lodged chiefly in the placenta, and produced there lesions that showed a tendency to heal. What other lesions were produced in the body of the mother we do not know. When she left the hospital she showed no signs of any other localizations, and unfortunately no additional history of her or her offspring has been obtainable. This report shows that even in the case of an unrecognized latent lesion in the lung of a pregnant woman tubercle bacilli may enter the circulation and produce a miliary placental tuberculosis. If this is possible it is also possible that under such circumstances the bacilli may pass the placenta and enter the body of the fetus. This case also emphasizes a point that I have made in previous papers on placental tuberculosis, that there is apparently some especial resistance on the part of fetal tissues to the tubercle bacillus, since tubercle bacilli have been found in large numbers in the liver and blood of infants without any histologic appearances of tuberculosis. The low virulence of the placental infection in this case may possibly be explained as the result of such a relative immunity on the part of the placental tissues. On the other hand, as the mother did not develop a miliary tuberculosis, the bacilli may have been of a feebly virulent strain (bovine?), or the number in the maternal blood-stream was small, and those found lodgment only in the placenta.

# ABDOMINAL ADHESIONS *

R. C. COFFEY, M.D.
PORTLAND, ORE.

Every surgeon of experience has been impressed by the fact that certain patients are apt to form extensive adhesions following the simplest operation, done under perfect aseptic conditions, while other patients fail to form adhesions no matter how much the traumatism, nor how imperfect the technic. He has also found that certain patients will seemingly withstand a great amount of sepsis, while others die from very slight infections.

I have done a great deal of experimental work in the abdomens of both hogs and dogs, and have been impressed by the fact that hogs form extensive adhesions with the slightest provocation, while dogs do not form extensive adhesions as a rule. I have been equally impressed by the fact that hogs rarely die of sepsis, while dogs are very susceptible to infection, as proved by the fact that the farmer unsexes his sows without any preparation; without even washing his hands, which often contain every germ known to bacteriology; uses a piece of twine which he may find in the barnyard for closing the abdomen, and yet rarely has suppuration in the abdominal wound, and almost never has an animal die from peritonitis; while on the other hand, it is found that in unsexing bitches under the same circumstances, the great majority of them die. In other words, the hog with his tremendous resistance and rapid reparative processes, forms adhesions, but these adhesions are the result of the same beneficent process which so perfectly destroys the septic material. On the other hand, the dog dies because of a lack of these elements and process which form adhesions. A statement may then be made, that it is better to be a live hog with adhesions than a dead dog without adhesions. Adhesions may play a beneficent rôle or a harmful rôle. The process is beneficent in the first place, but in certain instances the adhesions may become harmful after their beneficent office has been fulfilled.

* Read in the Section on Obstetrics, Gynecology and Abdominal Surgery of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

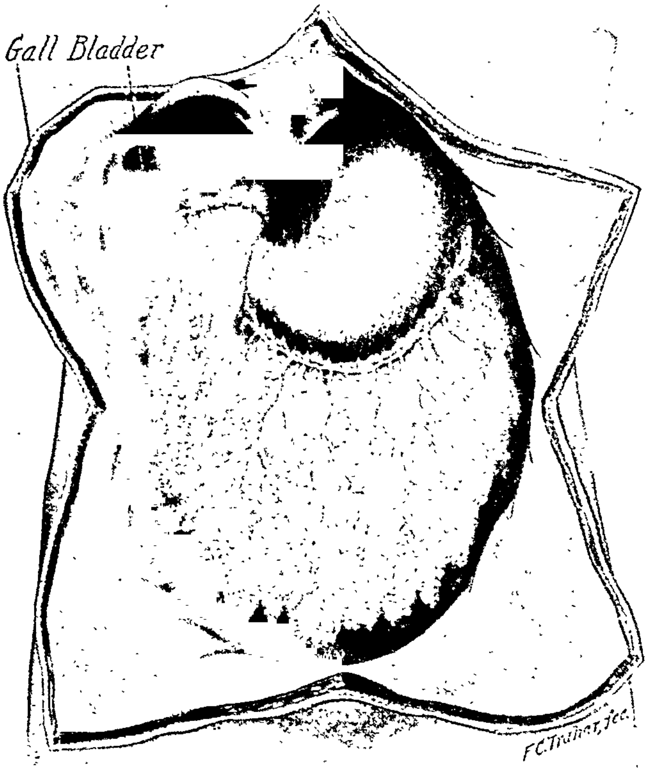

Fig. 1.—Reflected free edge of greater omentum sutured to lesser omentum for the purpose of separating the gall-bladder from the duodenum, thus preventing the reformation of adhesions.

It is true in all the practice of medicine and surgery, that the physician's work is chiefly auxiliary. He cannot prevent the formation of adhesions, and it is well; but he can modify an excess of adhesion forming, or remove the harmful adhesions after they have formed.

About four years ago the late Joseph Price read, before the Southern Surgical Association, a paper entitled "Surgical Junk," in which he discussed the postoperative adhesion question. "Surgical junk" is a very expressive term, for the adhesions following reparative processes simply represent material that was brought to the scene of action for a purpose, and now has no further use. I have had the literature of this subject completely abstracted at the Surgeon-General's office. The most striking features of the literature are in its monotony and its inconsistency. All authors have discussed prevention, e. g.: all authors have discussed the wet and dry protective pads, one maintaining that he had performed 132 laparotomies with dry asepsis, with ten deaths, five of which were due to intestinal obstruction, while in seventy-six cases treated with moist asepsis, he had two deaths and no intestinal obstruction. An equally prominent authority reported 481 laparotomies with dry asepsis, and only one fatality from ileus, while with moist asepsis he had a very much higher rate. Other operators assert that exposure to the air is the principal cause of adhesions; others that trauma is the principal cause, and still others that sepsis is the chief cause. Every variety of lubricant that has ever been known has been used by ardent advocates to prevent adhesions, and condemned even more ardently by others who have tried them. Some have used prepared membranes with good results, while others equally prominent get no results. Some have no adhesions by using cathartics; others get equally good results by absolute rest treatment. By carefully considering all the literature which has been written, along with my own limited personal observations, I think we may safely reach the following negative deductions:

1. The choice between the wet and dry pad is not vital, if equal care is used in their use.
2. Oils and all lubricants are worse than useless in the prevention of adhesions.
3. Specially prepared membranes and other foreign bodies have not proved equal to the claims of their advocates.
4. Cathartics following operation probably do more harm than good as a rule, although at times they may be of benefit.

On the other hand, we are safe in the following positive deductions:

1. Thorough asepsis.
2. As little handling as possible.
3. Avoidance of all traumatism and exposure to the air, as far as can be.

All of these agencies and precautions undoubtedly have an influence, but of greater importance is the special resisting power of the patient. Adhesions forming under given circumstances probably are in exact ratio to the patient's power of resistence to sepsis.

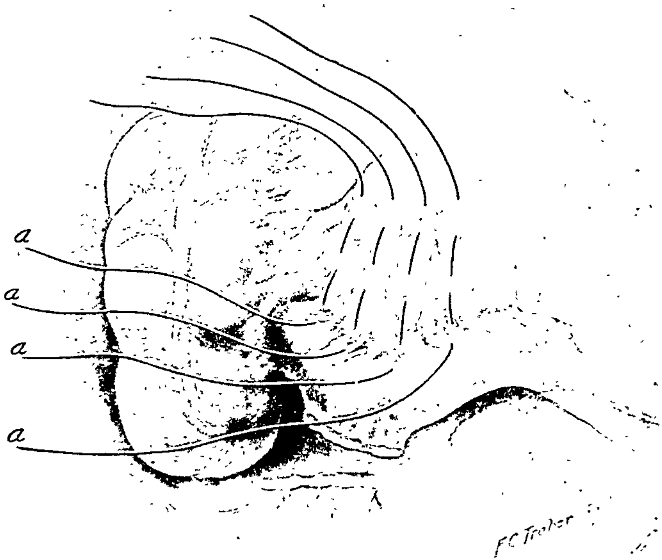

Fig. 2.—Method of applying purse-string sutures for the purpose of shortening the mesentery of the ileum to prevent reformation of Lane's bands; (a), purse-string sutures.

over the right upper in front. The back shows slight impairment over the right upper with slight increase in tactile fremitus, as well as of whispered and spoken voice. Expiration is somewhat increased over the right upper behind. No râles are heard.

*Tuberculin Tests.*—There is a slight reaction to 25 per cent. in ninety-six hours (von Pirquet).

*Subcutaneous Test.*—Two mg. of tuberculin were injected at 10 a. m., November 5; at 2 p. m., November 6, there was slight redness around area of injection, and area was very tender. Highest temperature was 99.2 F. Dec. 7, 1912, patient was given 5 mg. of tuberculin, subcutaneously. On noon of the following day, temperature reached 99.7 F., falling to normal toward evening. The area of injection was red, indurated and tender. No râles were heard.

Roentgenoscopy reveals slight increase of root shadows but no definite sign of tuberculosis.

Medical examination shows a positive tuberculin test, a suspicious right apex, but no evidence of active disease.

From these examinations it is evident that the patient has had an incipient tuberculosis of the right apex, now no longer active. It can be inferred that earlier in pregnancy this apical lesion was active for a time, and that bacilli then escaped into the blood-stream and into the interchorionic spaces. This assumption is supported by the character of the placental lesions. In practically every section made of this placenta there were miliary tubercles, in all respects characteristic histologically. The average section contained from four to six tubercles. Very few of these tubercles were recent ones. No absolutely fresh miliary thrombi, such as characterize the early miliary tuberculosis of the placenta, were found. The majority of the tubercles were epithelioid in type with a tendency to healing, as shown by the development of a more mature connective tissue in and about the tubercle, some of the tubercles appearing more fibroid than the connective tissue of the villi. Giant-cells were not frequent. Many of the tubercles showed no caseation or only a slight central caseous change; only a few showed a marked central caseation. Tubercle bacilli could not be found in the epithelioid and healing tubercles, but were demonstrated in small numbers in the caseating tubercles. There is, therefore, no doubt as to the nature of the process. The healing tubercles are easily distinguished from small infarcts by their sharply circumscribed borders and by the fibroblastic proliferation of the villi included in the primary intervillous thrombus to form a compact epithelioid mass. When transition stages from the earliest form of the placental tubercle up to the healing stage are present, as in this material, there is little likelihood that any one who is familiar with the histologic characteristics of placental tubercles would hesitate in immediate recognition of the nature of the process; but if the healing forms alone were present and in small numbers there might be difficulty in such recognition. There are, however, but two things that need to be considered in the differential diagnosis: small localized areas of syphilitic chorionitis and small infarcts showing reparative changes. In the former the syphilitic process involves only the stroma of the villi, and the villi are not fused into a solid fibroblastic or fibroid mass; in the healing infarct the villi may be fused, but there is no fibroblastic formation, or only the slightest, between them.

The healing tubercle, on the other hand, may show outlines of some villi fused into an intervillous epithelioid or fibroblastic proliferation. In this case all stages of tubercles were present, although the majority were in the healing stage, and the presence of tubercle bacilli makes the diagnosis absolutely certain, although the histologic changes are in themselves sufficiently characteristic.

This case, therefore, presents a placental miliary tuberculosis of a low virulence, the majority of the tubercles being in a healing stage. It is very probable, then, that in the earlier months of pregnancy, most likely in the third or fourth month, a latent tubercle in the right apex became active, gave access to the blood of tubercle bacilli that lodged chiefly in the placenta, and produced there lesions that showed a tendency to heal. What other lesions were produced in the body of the mother we do not know. When she left the hospital she showed no signs of any other localizations, and unfortunately no additional history of her or her offspring has been obtainable. This report shows that even in the case of an unrecognized latent lesion in the lung of a pregnant woman tubercle bacilli may enter the circulation and produce a miliary placental tuberculosis. If this is possible it is also possible that under such circumstances the bacilli may pass the placenta and enter the body of the fetus. This case also emphasizes a point that I have made in previous papers on placental tuberculosis, that there is apparently some especial resistance on the part of fetal tissues to the tubercle bacillus, since tubercle bacilli have been found in large numbers in the liver and blood of infants without any histologic appearances of tuberculosis. The low virulence of the placental infection in this case may possibly be explained as the result of such a relative immunity on the part of the placental tissues. On the other hand, as the mother did not develop a miliary tuberculosis, the bacilli may have been of a feebly virulent strain (bovine?), or the number in the maternal blood-stream was small, and those found lodgment only in the placenta.

ment (Fig. 6); (*c*), in cases of ptosis which existed prior to an inflammatory process, by which process the omentum has been firmly fastened to the pelvic organs or to an operative wound in the lower abdomen, in such a way as permanently to fix the stomach and transverse colon low down in the pelvis, and thus prevent their proper emptying (Fig. 5). In these cases the greater omentum is sutured to the abdominal wall midway between the umbilicus and ensiform cartilage, and the upper abdomen expanded, thus curing the ptosis as well as the evil effects of the adhesions.

4. In cases of excessive adhesions in the pelvis or other parts of the abdomen, in which a loop of intestine goes into a mass of adhesions and emerges, leaving plenty of clear intestine above and below, by far the best plan is to leave the adhesion alone and short-circuit by making a lateral anastomosis between the two limbs, as shown in Figures 7 and 8, which operations I have done repeatedly, when the adhesions had gone to the point of producing intestinal obstruction. I may state that all of these patients have remained in perfect health, although the adhesions were permitted to remain without disturbance.

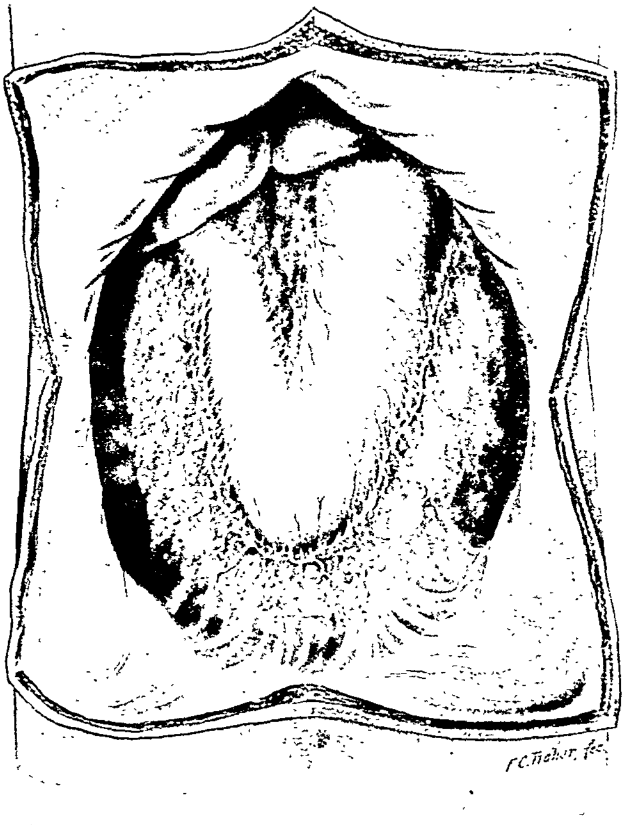

Fig. 5.—Midline ptosis made permanent by adhesion of the greater omentum to the lower abdominal wall or pelvic organs following inflammatory condition or surgical operation in patient who was previously afflicted with ptosis.

5. In addition to the foregoing methods, I now submit a fifth method of treating adhesions in well-marked adhesion-forming patients, in whom adhesions recur after operation, in increasing quantity. It is the insertion of a protected gauze pack. For the past ten years I have used a gauze pack in certain septic conditions, with a great deal of satisfaction. In my early cases I used the gauze wicks without protection, which had the disadvantage of sticking to the loops of intestine and often paving the way for subsequent hernia, for I found that in a little over 25 per cent. of cases thus drained developed hernia later. During the past six years I have protected the gauze pack by several layers of rubber tissue, and by so doing I find in examining my records that the hernias have been reduced to a little more than 5 per cent. This drainage has been used in cases of acute sepsis, involving an area which could not be removed. I have used this pack during the past ten years in more than two hundred cases. In cases in which it has been necessary to open the abdomen for some other reason afterward, I have been particularly struck with the fact that adhesions are absent to a remarkable degree, and I believe I am safe in saying that the adhesions are less than in the average clean case in which the abdomen is closed without drainage. After observing this absence of adhesions following the use of the quarantine pack, I decided

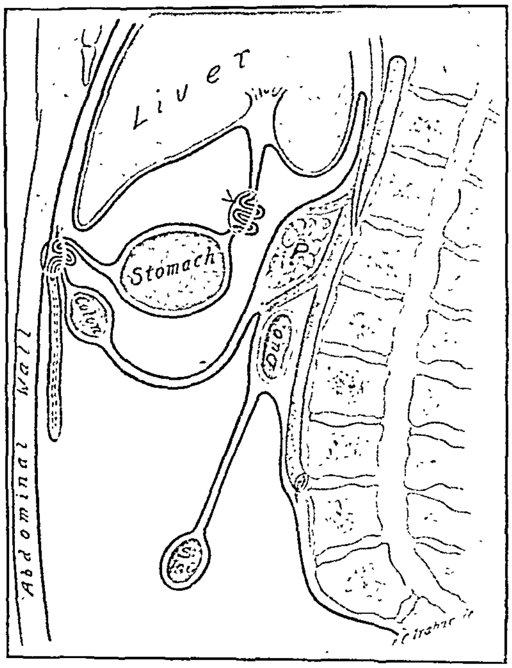

Fig. 6.—Lesser omentum shortened (Beyea). Greater omentum sutured to abdominal wall (see *Surgery, Gynecology and Obstetrics*, October, 1912).

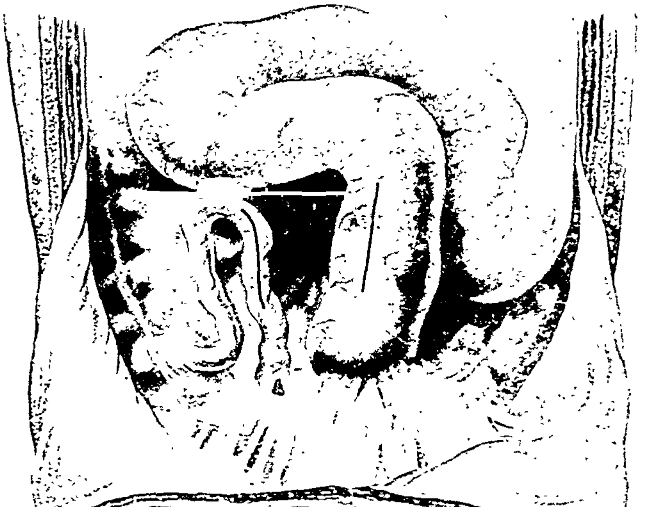

Fig. 7.—Relief of complete obstruction, due to extensive pelvic adhesions, by short-circuiting.

o try it for cases of extensive adhesions, in which the patient had been repeatedly operated on. Every surgeon knows these cases, and knows how he opens the abdomen, dissects adhesions sometimes for hours, possibly opens the intestine several times, closes the intestinal wounds and closes the patient with fear and trembling, expecting sepsis to follow. Sepsis does not follow; the patient recovers temporarily, but soon begins to show evidences of the reformation of troublesome adhesions. He finally opens and repeats his dissection with the same results. In this class of cases the protected gauze pack does its best work. It is placed as follows:

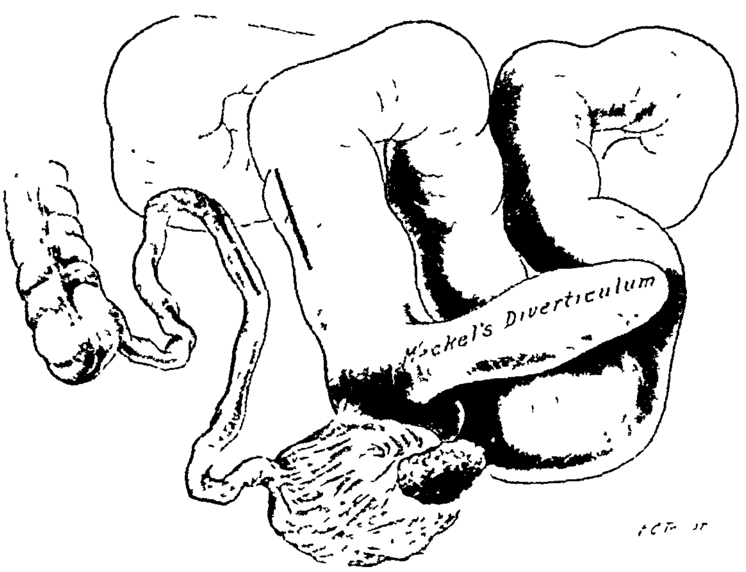

Fig. 8.—Relief, by short-circuiting, of complete obstruction due to adhesion of intestines around a mesenteric stone which weighed a little more than 2 ounces. Note Meckel's diverticulum.

### TECHNIC OF GAUZE PACKS

All the intestines must be temporarily packed far away from the infected or denuded area or organ. Gauze wicks the size of a finger should be laid straight, side by side, reaching entirely across the abdomen and coming out through the drainage opening. Four or five layers of gutta-percha tissue are then placed above the gauze and allowed to come out through the opening also. The intestines are now allowed to come down against the rubber tissue (Fig. 9). The omentum is drawn down, and if long enough is interposed between the rubber tissue and intestines (Figs. 10 and 11). The pack is brought out at the lower angle of the wound, and the upper part of the wound closed snugly around it, with combined layer and through sutures.

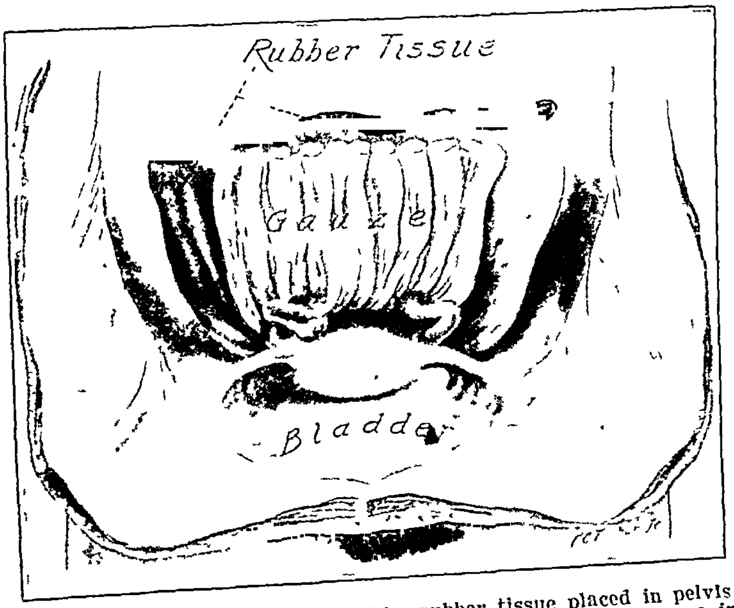

Fig 9—Gauze wicks protected by rubber tissue placed in pelvis Note that an infected tube has been split and allowed to come in contact with the drain. This procedure is not advisable in gonorrheal pus tubes

In my experience it has been better to attempt to remove half or all of the gauze wicks about the sixth or seventh day after the drain is placed. If the gauze is removed before the end of six days, it is usually done with difficulty. If it is allowed to remain more than ten days it again attaches itself and is removed with difficulty, so that at the end of about six days it will usually be found that the wicks are pulled out more easily than they are either sooner or later. At times I remove all of the gauze at this date, and at other times leave about one-third of it and take it out about three days later. I rarely remove the rubber tissue earlier than ten days or later than fourteen days. At this time I remove all of the rubber tissue and slip in a small soft rubber tube, tapered at the end, which prevents the adbomen from closing over the cavity before it is healed. This is allowed to remain a week or ten days, until the bottom of the opening has time to close in around the tube and make a straight sinus. If this last tube is not allowed to remain long enough, the wound heals on the outside and leaves a large unhealed cavity on the inside, which makes the wound very much slower in closing

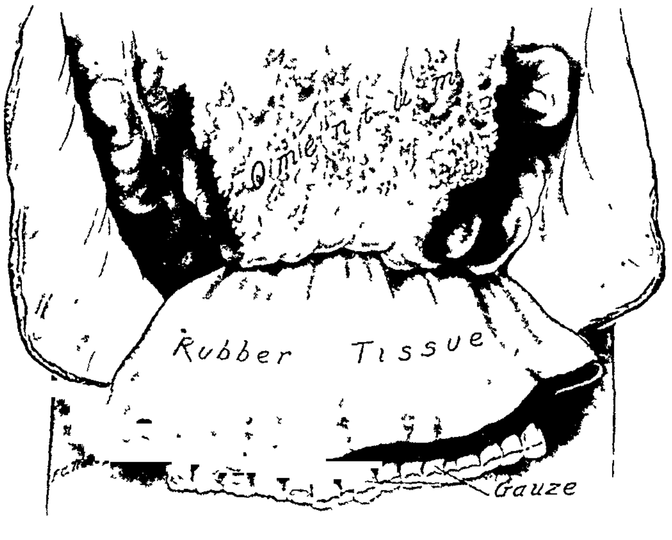

Fig 10—Protected gauze pack has been placed and omentum interposed.

About five weeks is the average time for a wound thus treated to heal entirely. I usually keep the patients in bed for about four weeks.

No procedure in all of my abdominal work has given more complete satisfaction. In no case has it ever been necessary to reoperate for adhesions after the use of the protected pack. The pack seems to serve two purposes. First, it rapidly drains off serum, and with it the adhesion-forming plastic material, which seems to be excessive in these adhesion-forming patients, so that there is not much material to form adhesions. Second, it creates double lines of granulation, which apparently are incapable of uniting with each other firmly.

789 Glisan Street.

### ABSTRACT OF DISCUSSION

Dr. J. H. Jacobson, Toledo, O.: Dr. Coffey's theory seems to me in direct contradiction to our ideas of the formation of abdominal adhesions. The work done by Dudley and Sargent is the best on this subject. They point out that adhesions are formed from plastic exudate thrown out on the intestinal walls about the site of the operation. They maintain that with proper drainage and removal of the serum and exudate adhesions are prevented. The other principle is that the introduction of all foreign substances or anything which will destroy the endothelium of the peritoneum will produce adhesions. The conclusions of Dr. Coffey seem to me in contradiction to these principles.

Can we account for the formation of adhesions in these cases? Will a timely operation, even in the presence of an enormous amount of infection, with properly placed drains lessen the tendency to adhesions? We can prevent the further destruction of the endothelial covering of the peritoneum and prevent adhesions? This is a most important principle and one which we should work on in doing abdominal surgery. It is important to do away with dry packs and to use the moist. In the gall-bladder operation, with the use of the Mayo-Robson position the abdomen is closed before the patient is put back in the horizontal position. We have noticed adhesion of the liver to the parietal peritoneum and part of the diaphragm. We have separated the adhesions and used the omentum. When it is necessary to use a substance to prevent adhesions in the abdominal cavity, Dr. Coffey has shown that he prefers that method to the use of foreign materials. I also wish to mention the danger of adhesions from the contact of the intestines with the iodin. Because of this, the skin should be covered with gauze so that the intestines will not come into contact with the skin. I am much interested in this quarantine pack because we are introducing into the abdominal cavity foreign material, and yet, apparently, with the draining off of the serum we prevent the reformation of adhesions. This is contrary to the usual view of the formation of adhesions. We must wait and hope that it will prove to be as Dr. Coffey has told us to-day.

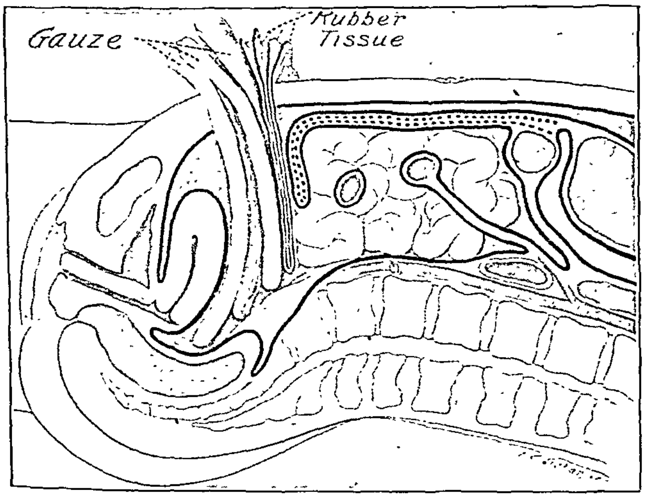

Fig. 11.—Scheme of protected gauze pack as applied to the pelvis for the relief of extensive adhesions.

Dr. John B. Deaver, Philadelphia: I have saved many lives by the procedure described by Dr. Coffey. I have had thirteen cases following appendicitis. All the patients were operated on and all recovered, and I did not interfere with the adhesions at all. That is masterly inactivity, conservative surgery. More radical surgery would be likely to result in disaster. In place of the quarantine pack, we formerly used rubber tissue. The principle is the same. There is no question at all that the convalescence is less interrupted and more permanent. I was also glad to hear Dr. Coffey say that he did not take the gauze out until from the sixth to the eight day. I tell my house-doctors to leave it in until it practically comes out.

Dr. Rufus B. Hall, Cincinnati: This gauze protection in pus cases is a life-saving operation. Do not be afraid of adhesions if you use gauze. I have used this method for twenty years. I did not at first protect with rubber tissue, but find it a distinct advantage. I learned early in my work not to remove the gauze too soon. I handle it as Dr. Deaver does and wait until it becomes loose; in from six to seven days it can be removed easily. The hernia, if it occurs, can be treated afterward without trouble. I tell my patients that I expect them to have a hernia, but that it can be repaired. By this method we can save lives that would otherwise be lost.

Dr. C. E. Cantrell, Greenville, Tex.: Do not break up these adhesions, if you can secure a loop of intestine for anastomosis, because otherwise some of the bowel will be denuded of its peritoneal covering. I have worked for hours trying to cover raw surfaces with peritoneum. I have in mind a case in which we operated a fourth time. We did not disturb the adhesions, but did an anastomosis and the man recovered.

Dr. Henry Boxer, Birmingham, Ala: The principal thing in abdominal surgery in the prevention of adhesions is to cover all raw surfaces, no matter how much time it takes, unless the patient's condition is bad and we have to finish the operation in a hurry. In pelvic surgery, when adhesions of the intestines are extensive, Dr. Coffey has mentioned that he does not disturb the adhesions, but makes an end-to-end anastomosis. If there is no obstruction to the intestines, the best plan is to leave the adhesions alone rather than to disturb them by making an end-to-end anastomosis, which sometimes proves disastrous to the patient.

Dr. R. C. Coffey, Portland, Ore.: The man who knows nothing but the drainage-tube and can use nothing else evidently does not cover the fundamental principles of drainage. The man who can use nothing but gauze and does not know when and when not to use gauze is not familiar with the fundamental principles. I think that the most exhaustive study I ever made on anything was on the matter of drainage in following the work of Clark and Yeats. They both reached the conclusion that drainage was a bad thing. They said it would not drain pus and blood, that it created a great deal of serum and was liable to infection. I admit that it forms serum in exact proportion to the amount of peritoneum that is touched by the foreign body, but the serum is brought there to form adhesions, and if we deliver it slowly by a small wick of gauze we shall produce more adhesions than if we had not touched it. On the other hand, if we drain the serum off as rapidly as it is formed we rob this area of all its adhesion-forming substance. That serum, however, is brought to the surface only in proportion to the amount of gauze that comes out through the wound. Clark used a pack of gauze folded on itself like the folds of a fan. He found large amounts of serum and adhesions after this method of drainage because it produced a large amount of serum and delivered only a small amount to the surface. If we put in enough to deliver the serum as fast as it forms, we have nothing with which to form adhesions. This is not true in the treatment of sepsis. There it is possible to operate in the most acute case with immunity. I did not have a fatality in six years when I used the method in acute pyosalpinx in which there was pus. If we deliver this serum to the surface as fast as it is formed, we keep the intestines back and have no adhesions. We do not find out by theory, but by having to reoperate in cases in which we have drained in this way. In these cases we find almost complete absence of adhesions, while, in cases drained by a simple tube or a small piece of gauze, adhesions are numerous. This, therefore, is the principle we must deal with.

---

**Health Ordinances with Inadequate Appropriations.**—This disposition on the part of our lawmakers to demand brick of the medical profession without having furnished any straw with which to make it, is almost too ridiculous for judicious discussion. The city of Fort Worth, for instance, after many years and in answer to the earnest demand of the women of the city, agreed to establish a board of health, consisting of five members, two of whom must be physicians, with advisory authority only and to serve without pay. At the same time, the commission agreed to pay a lawyer $1,000 to prosecute a case of alleged graft, and to extend to him actual authority. The difference is that there were no fanatics to rise up in their indignation and charge somebody with something in opposing the proposition. Doubtless similar conditions exist in other cities, and it is to be hoped that in the course of time public opinion will bring about a wholesome change of policy in this respect.—Editorial *Texas State Jour. Med.*

# A COMPARISON OCULAR.*

DANIEL J. HEALY, M.D.
LEXINGTON, KY.

While working on certain changes in the tissues of the guinea-pig, it proved of great advantage, in observing the finer changes, to use two microscopes side by side, one showing the normal tissues and the one the abnormal tissues. On Jan. 29, 1912, I communicated with Mr. Edward Bausch, suggesting that a microscope be so equipped with two objectives, "that on looking through the eyepiece one would see half of the field of each objective." The Bausch and Lomb Optical Company kindly worked out the idea, using, however, two microscopes and one comparison ocular, which method is more practical and less expensive than that of two objectives on one microscope.

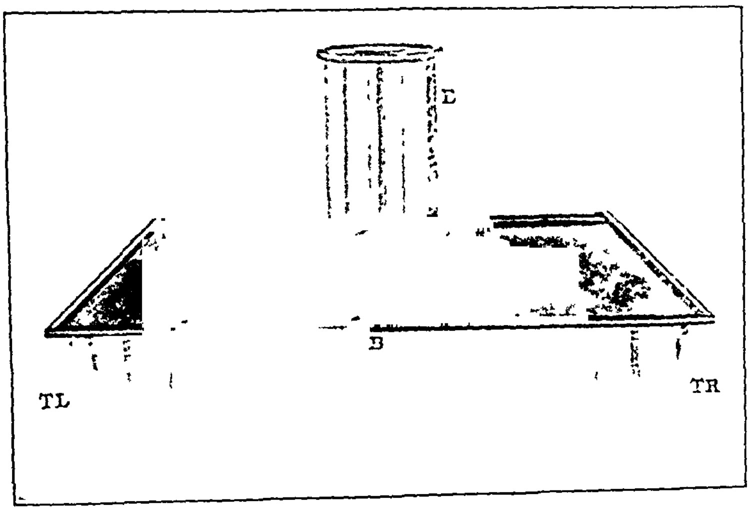

Fig. 1.—The comparison ocular. The ocular consists of a set of reflecting prisms within the box *B*, which carries the eyepiece *E*, in the middle, and a short tube at each end, marked *T-L* and *T-R*. The tube *T-L* fits snugly into the body tube of the microscope stand to the left, while the other tube, which is of smaller diameter, moves freely within the body tube of the stand to the right.

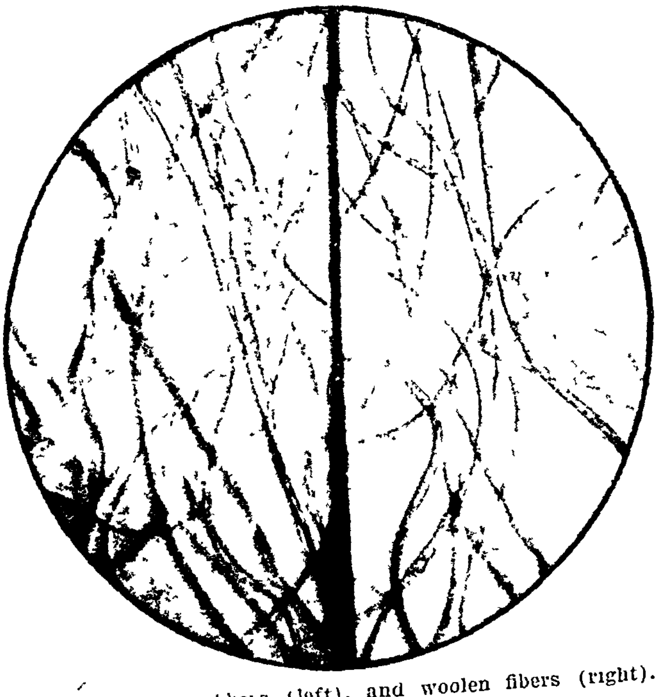

Fig. 3.—Cotton fibers (left), and woolen fibers (right).

The purpose of the comparison ocular is to permit the examination, side by side in the same field of the microscope, of two specimens, as, for example, a normal tissue and a pathologic tissue, the field being divided into two halves in which the objects on the stage are imaged, the images being separated by a straight line.

Two identical microscopes are placed side by side (Fig. 2), the draw tubes are removed, and the collars of the body tubes replaced; the comparison ocular is now attached by fitting the short tube *TL* snugly into the body tube of the instrument to the left, at the same time slipping the loosely fitting tube *TR* into the body tube of the instrument to the right. To avoid binding, the tube of the instrument to the right must be nurled down until the objective nearly touches the slide. Then the left instrument, which carries the ocular, is focused, after which the right instrument is focused with an upward motion.

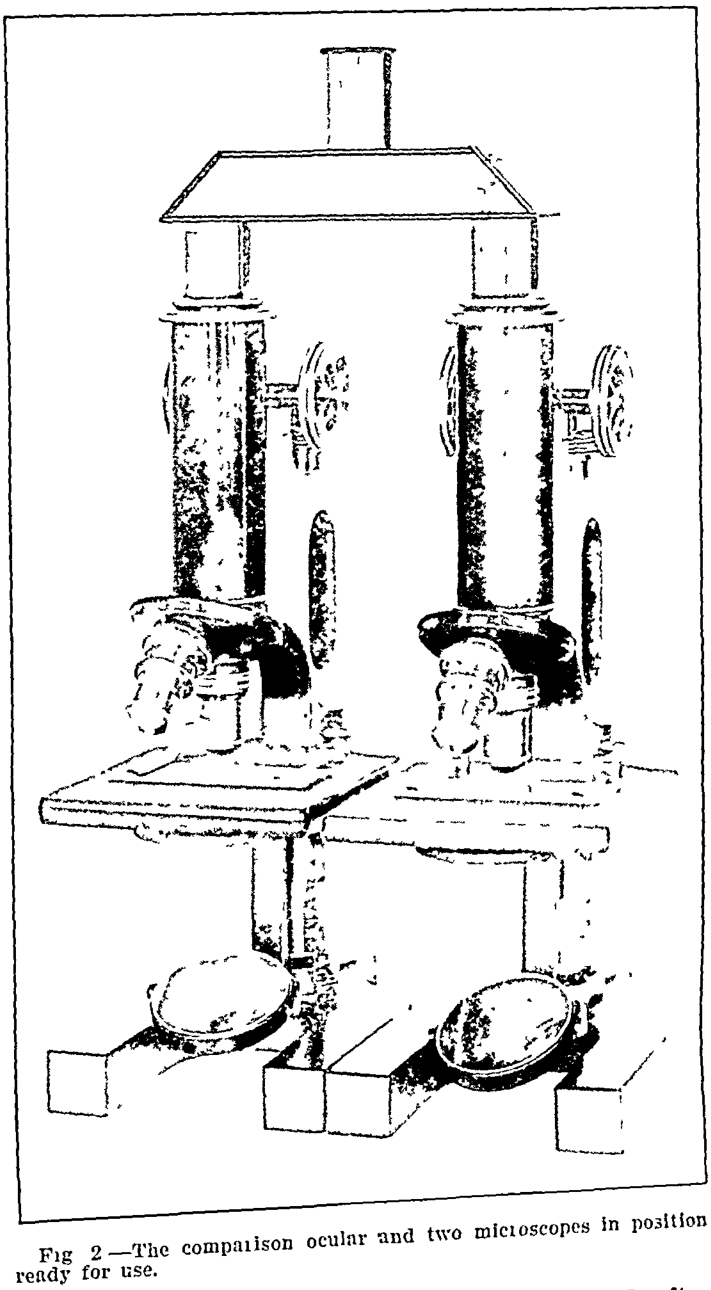

Fig. 2.—The comparison ocular and two microscopes in position ready for use.

The following illustrations are photomicrographs taken through the comparison ocular; direct diffuse daylight, from a north window, was used to illuminate the field; 16 mm. lenses were used, which with the comparison ocular gave a magnification of seventy-five diameters; the exposure was forty seconds.

The comparison ocular has been in use in this laboratory since May, 1912, and has proved valuable. Recent articles describe a comparison microscope devised in Ger-

many by Dr. W. Thörner.[1] As will be observed, we were using the comparison ocular six months before Dr. Thörner's article was published. The comparison ocular has the advantage in that it does not require a specially constructed microscope like the German instrument. thus being much less expensive and quite satisfactory in operation.

# MYOTONIA ATROPHICA *

FOSTER KENNEDY, M.D., F.R.S. (Edin.)
Chief of the Neurological Clinic and Instructor in Neurology, Cornell University Medical College
NEW YORK

The rarity of this curious muscular degeneration is the excuse for the report of a single case. Myotonia congenita, so-called Thomsen's disease, is not very uncommon, but the combination of increased tonus in some muscles with a primary flaccid palsy in others in remarkably constant distribution is so rare that but four cases have been reported[2] as yet in the medical literature of this country.

The disease is apparently peculiar to persons in middle life, is of a very slowly progressive character, and, in rather more than half the number of cases, is of familial type. The symptom-complex is so constant and so characteristic that, when once understood, recognition of subsequent cases becomes simple.

## REPORT OF CASE

*History.*—G. F., an unmarried Swiss, aged 46, was admitted March 27, 1913, to the Cornell Division of Bellevue Hospital, New York, and was placed under the care of Dr. Gilman Thompson.[3] The patient's parents had both died in old age. Three brothers and three sisters were in good health, but one sister, a resident of the United States, had arthritis deformans. There was no neuropathic family history. Neither the patient nor his sister knew of any near or collateral relative affected in any way similarly to the case under consideration. For fourteen years he had been employed as a farmer in New England. His habits were regular and his general health good. His consumption of alcohol was limited to two or three glasses of beer a day. He denied having had any venereal disease and said that his previous health had always been good.

In 1893 his left cornea was injured by a spark which fell on it from a passing engine. In 1887 his hands and feet are said to have been frost-bitten. In November, 1911, after hard work during a heavy harvest season, he began to have cramplike pain in the lumbar region. These pains were at first intermittent and rare, but later became more frequent, so that at the time of examination he constantly complained of their presence. He could remember no injury that would account for this condition, which became more severe when he worked in a bent posture. He strenuously denied having any difficulties in his gait or in the use of his hands. There were no sphincter troubles. He had not worked for a year but had never been confined to bed.

*Examination.*—The patient's facial appearance was quite strikingly characteristic of the disease, and was the result of an incomplete ptosis of both eyelids, with marked hollowing of the temporal fossae and flattening of the masseteric region on each side (See illustration). The orbicular muscles were very weak and there was no movement in the temporal or masseter muscles. The left pupil was hidden by a corneal scar, the result of the injury previously spoken of. The reaction of the right pupil was normal. A well-marked and advanced attacks" in which he became greatly depressed. When he consulted me in December, 1904, he was complaining of indigestion, characterized by belching and peculiar pressure sensations which seemed to "radiate from the stomach upward through the chest and arms." These symptoms seemed to bear no relationship to the character of the food taken, but usually occurred one or two hours after meals, unaccompanied by pain or vomiting. At this time 26 pounds in weight had been lost within a period of four months. The appetite was not good. The bowels were regular, but not free, sometimes compelling the use of enemas. At times there was palpitation, which the patient attributed to "gas in the stomach." There was no dyspnea, edema or any nocturnal urination. From time to time dizziness was experienced on sudden change of position.

[3] Dr. Thompson kindly asked me to see this case, and by his courtesy I am permitted to use these notes.

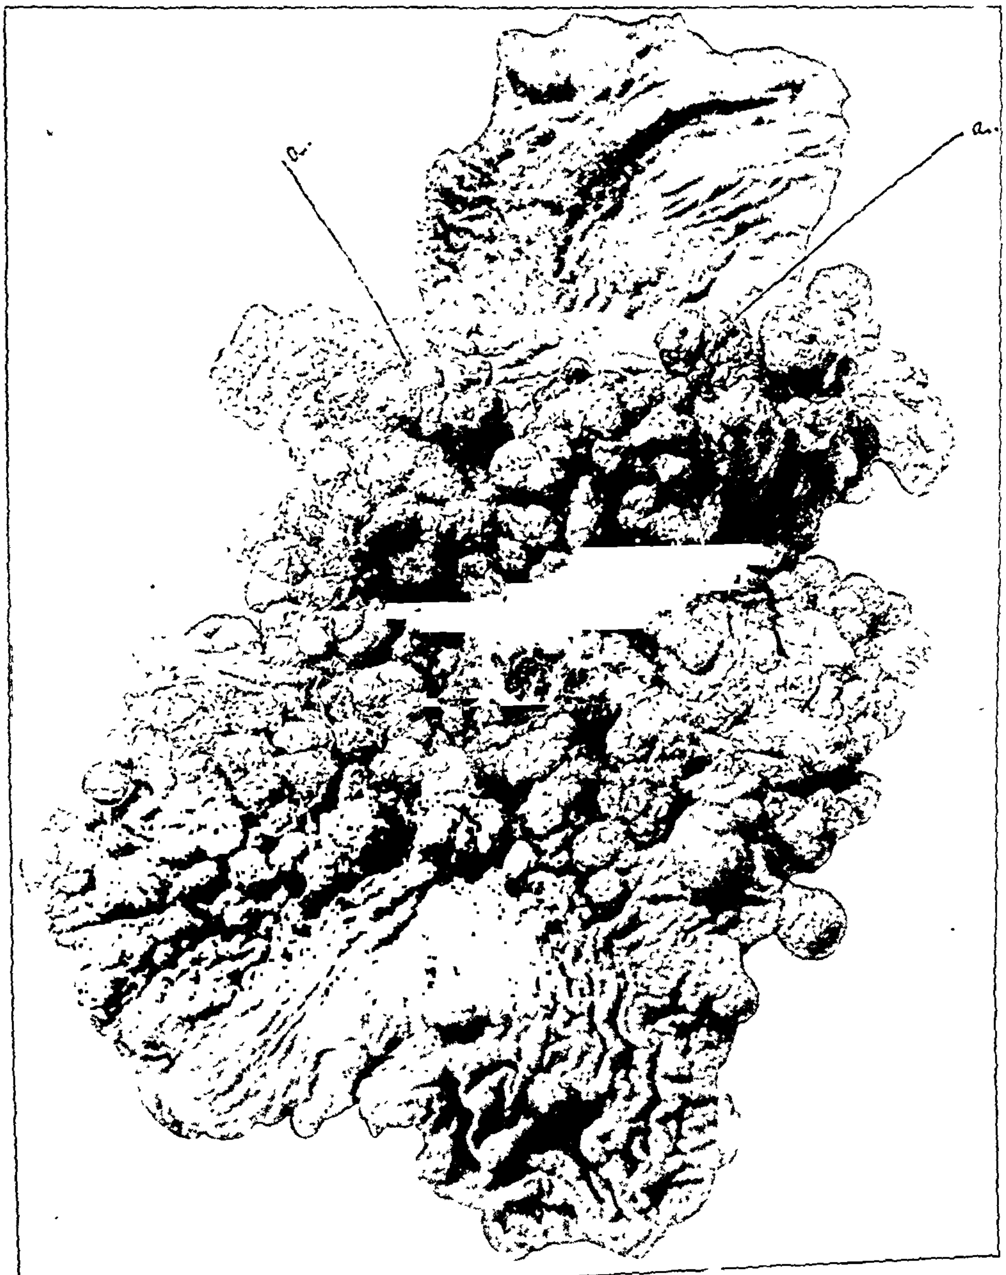

Fig. 2.—The stomach removed at necropsy showing the entire mucosa, with the exception of a small area near the cardiac orifice, literally covered with polyps; *a*, a large grape-like bunch of polyps, a portion of which had invaginated the pylorus.

*Examination.*—The patient was a man of medium height, of a florid complexion, weighing 178 pounds, still well nourished though showing evidence of loss of weight. The pupils reacted normally to light and accommodation. The patellar reflexes and the sensorium were normal. There was a low systolic murmur at the apex of the heart, not transmitted. There was no enlargement of the heart. The lungs were negative. The liver was palpable two fingers' breadth below the free margin of the ribs on deep inspiration and was of normal contour and consistency. There was no pain on pressure in the right iliac, right hypochondriac or epigastric region. At the diaphragmatic insertion were numerous small dilated vessels. There was no tumefaction, though the epigastrium bulged slightly and presented slight resistance to pressure. Inflation of the stomach revealed no enlargement or displacement. There were a few enlarged lymph-nodes in the left anterior cervical region and also in the groins. On the dorsum of the penis was a small non-indurated scar and a scar was also on the left hand, the result of the lesion previously mentioned. The urine was negative. Hemoglobin, 67 per cent.

After a test-breakfast removed Dec. 14, 1904, 1½ ounces of slightly acid contents were recovered, with free and combined hydrochloric acid entirely negative. Lactic acid was mildly positive. There was a slight increase in mucus. Microscopically, nothing was abnormal. Test-breakfasts taken Dec. 16, 18, 20 and 24, 1904, and Jan. 10, 13 and 24, 1905, constantly revealed normal motility with complete achylia gastrica and a slight increase of stomach mucus. The diagnosis of chronic, atrophic gastritis was entered at this time into the records.

*Treatment and Course.*—This was prior to the days of the Wassermann reaction, so in view of the history of the case and the presence of abnormal fundus findings as reported by the oculist, iodids were given, which were tolerated so badly that the patient soon discontinued them. He took an extended trip, and on his return home stated that he felt fairly comfortable. I did not see him again for a period of five years, during which time the general condition was such that he felt no need of consulting a physician.

The patient returned in February, 1909, complaining of pronounced gastric symptoms, characterized by intense pressure in the epigastrium from one-half to one hour after meals, followed by "gas pains," three or four hours later. He was often compelled to get up during the night and walk the floor until he could free himself of the gas accumulation.

Physical examination at this time revealed no particular variation from the previous examination, except, perhaps, that the general nutrition was much improved. There was, however, a marked change in the gastric contents, which still contained no hydrochloric acid and no pepsin, but abounded in large quantities of mucus. Many analyses were made between February and October, 1909, with practically the same findings. The mucus was much like finely divided, slightly coddled white of egg. It was practically impossible to lavage the stomach long enough to obtain wash-water free from mucus. Microscopically, there was an increase in yeast, though there was no branching. Almost invariably there were a few red corpuscles, many undigested and partially digested leukocytes, many long and short bacilli and at times traces of pepsin, varying from 14 per cent. to 40 per cent. (Hammerschlag). There was no food retention. Numerous examinations of the feces revealed no blood.

The patient obtained his greatest relief through lavage, which was given now at frequent intervals for several months. The quantity of mucus that could be obtained from the fasting stomach was simply amazing. Not infrequently the wash-water was tinged with blood toward the end of the process of lavage. This, naturally, was assumed to be due to the irritation of the diseased mucosa by the tube. In view of the fact that the ocular conditions were gradually getting worse, and on the assumption that the gastritis might be of luetic origin, the patient was given mercury injections and iodalbin, which were very well tolerated.

During the latter part of 1909, while the stomach was being lavaged, a small polyp about the size of a pea was expressed through the tube. It was perfectly round, smooth and unaffected by digestion, and showed definitely where the pedicle had separated. A microscopic examination showed it to be a simple benign adenoma. This naturally led to the supposition that there might be other small polyps in the stomach.

In 1910 the patient complained frequently of vertigo and this was attributed to the eye condition. There were also occasional attacks of diarrhea. A blood examination at this time revealed hemoglobin, 80 per cent.; leukocytes, 21,800; erythrocytes, 6,192,000; polynuclears, 67 per cent., large mononuclears, 16 per cent.; lymphocytes, 12 per cent.; eosinophils, 5 per cent., and red cells normal in appearance.

Test-breakfasts examined from time to time in 1910 revealed perfect motility, immense quantities of mucus containing many leukocytes, a total absence of hydrochloric acid and a mild degree of peptogenic power.

In the summer of 1911, while up North fishing, the patient developed an edema of the extremities and a rather marked degree of dyspnea, due to a relative insufficiency of the mitral valve, the result of overexertion. The condition improved under rest and digitalis, and when I saw him again in August he had a rather marked systolic murmur and intermittent heart-action, with an accentuation of the second pulmonic sound.

March 5, 1912, while in a hotel rotunda, the patient was overcome by a feeling of faintness and vertigo and fell unconscious. Shortly after this he vomited large amounts of blood, much of which was clotted. Before he could be removed to the hospital he had a large, perfectly black bowel-movement. Those present at the time think that he vomited at least a quart of blood. As soon as possible the patient was taken to the hospital. Temperature, 98.4; respiration, 20; pulse 120. There was no further vomiting, but the stools contained very large quantities of changed blood.

On the first examination at the hospital there was visible peristalsis and a palpable resistance in the pyloric region, much resembling the consistency of liver. On the following day with the hand resting lightly over the pyloric region to see if the peristalsis could be palpated, one could feel periodically the stiffening of the pylorus, and this was immediately followed by most peculiar movements under the hand, which resembled the movements of the small parts of a fetus. By stethoscope the movements could be heard as a distant rumbling noise followed by a squirting sound, as of a mixture of fluid and gas. The patient stated that the sensation could be experienced by fixing the mind on it, and, without any suggestion on my part, he described it "as the opening and closing of a valve." In view of this peculiar phenomenon, together with the previous findings of a small polyp in the washings, I concluded that a pedicled polyp had invaginated the pylorus, extended through into the duodenum and that either through laceration or the separation of a portion of it hemorrhage had resulted. The stools were watched carefully, and within three days a portion of a polyp about the size of a walnut was found, irregular in outline, with the surface partially digested. Sections were made which revealed the typical structure of a gastric polyp. A soft resistance could still be felt at the pylorus, but the peculiar movements described above became less apparent, though they remained more or less so throughout the early convalescence.

The treatment consisted in absolute rest, the application of ice-bags to the epigastrium, calcium chlorid by rectum, morphin hypodermically and fluids by rectum during the first forty-eight hours. Fluids were given by mouth on the third day in small quantities which were gradually increased until about the sixth day, when liberal amounts were taken.

Blood was apparent macroscopically for about ten days in the stools, but gradually disappeared, and within three weeks after admission to the hospital there were no chemical traces of blood to be found.

The patient complained more or less constantly of "gas in the stomach" and considerable distress, though of very little actual pain. The pulse remained around 90, until about the twelfth day, when it began to resume the normal. On the twenty-sixth day he sat up and was taking liberal quantities of soft food. At no time throughout his convalescence was there any evidence of food retention. There was no vomiting, no eructations, and in spite of the liberal quantities that were administered in an effort to build up the system as rapidly as possible, there was no stagnation.

March 31 his weight, which had usually been in the neighborhood of from 165 to 170, was 137½ pounds. Following the primary hemorrhage the hemoglobin was 35 per cent. A month later the hemoglobin ranged from 50 to 60 per cent., the erythrocytes 4,264,000. About this time the tertian type of plasmodium was found when a routine examination of the blood was made, and before treatment could exert sufficient influence, the temperature suddenly went up to 101, the patient had a severe chill, and the hemoglobin dropped to 40 per cent. Under quinin the plasmodia soon disappeared. This was during a month when we have no mosquitoes in St. Louis, and while there was no history of malarial infection, the plasmodia were evidently latent in the bone marrow and had probably been liberated as a result of the rapid activity brought about through the acute hemorrhage. By the early part of June the patient's condition was excellent. The hemoglobin was now 84 per cent., the erythrocyte count 6,488,000, and the blood-findings in general practically normal. The weight was now 158½ pounds, a gain of more than 20 pounds from the first weighing one month after admission to the hospital.

The fluoroscopic and roentgenographic examinations of the stomach revealed an almost total obliteration of the pars pylorica and the median portion of the fundus. The bismuth mass formed a shadow to the left of the vertebral column, showing a very irregular and indefinite outline. The bismuth in trickling through the interstices showed a very dim shadow of the right half of the stomach. The mottling of the bismuth shadow in this portion of the stomach suggested irregular masses in the stomach wall (Fig. 1). The length of time required for the stomach to empty itself was not determined, but there was apparently no retardation, as is evidenced by the bismuth shadow in the small intestines within fifteen minutes after the ingestion of the bismuth.

Though immediate operation following the hemorrhage was considered, the patient seemed such a poor risk and improved so rapidly on rest, diet and iron medication that it was decided to defer it as long as improvement continued. Early in June he felt quite himself again. On the basis of the previous literature and the palpatory findings following the patient's hemorrhage, it was thought probable that there was one large polyp attached near the pylorus and extending through it, and that there were probably a number of smaller ones grouped about the large one. It was hoped, therefore, that a gastrotomy could be done and the polyps removed individually or by a resection of the polyp-bearing area.

*Operation and Result.*—June 17 a median incision was made by Dr. Max W. Myer, a small amount of free fluid escaping. The liver presented itself, somewhat enlarged, but soft. Adhesions were found at the greater curvature about 3 inches from the pylorus, which when detached revealed an area of small, dilated vessels or varicosities on the peritoneal surface. There was some contracture at this point, which presented an hourglass appearance. Palpation of the stomach revealed a large, soft, putty-like tumor mass easily the size of a man's fist, occupying the median portion of the stomach lumen. Further palpation revealed similar smaller masses filling more or less the lumen of the stomach up to the cardia. Only a small portion of the pyloric end seemed free from involvement. Resection seemed out of the question. The stomach was opened over the large tumor mass by an incision parallel to the greater curvature, the pyloric and the cardiac ends of the stomach first being clamped with rubber-covered clamps. When the stomach was opened a reddish-brown papillomatous growth began to deliver itself, and a tumor larger than a man's fist with much the appearance of a bunch of grapes was gradually delivered, the pedicle of which corresponded to the area of contracture noted on the greater curvature before the stomach was opened. The pedicle was half the length of the index-finger. In addition to this, the mucous membrane of the stomach from the cardia to within an inch of the pylorus was literally covered with small pedicled polypi, varying from the size of a large pea to that of a hazelnut. In view of the extensive involvement of the mucous membrane, a complete resection of the stomach was practically impossible. In the meantime, the patient's condition became very unsatisfactory. It was decided, therefore, to remove the large papillomatous growth only. After this was done, an attempt was made to close the incision in the stomach, first overwhipping the mucous membrane with catgut. The stomach was closed with several layers of chromic gut, buttonhole stitch and finally with a layer of silk, stitching the omentum to the suture line.

The patient's condition when he left the table was very bad indeed. Shortly after returning to bed he vomited a considerable amount of blood which included several small polypi. There was constant oozing of blood throughout the day, either from the incision or from the pedicles of the detached polypi, and in spite of every effort the patient died about twelve hours after the operation.

*Necropsy.*—This revealed little of interest outside of the stomach (Fig. 2), which, together with a portion of the duodenum and of the esophagus, was removed, and contained a large quantity of clotted blood. There were enlarged lymph-nodes in the gastrohepatic omentum and the mesentery. Intestinal polypi were not present.

I am greatly indebted to Dr. E. L. Opie for the following notes with the results of his macroscopic and microscopic findings.

*Gross Examination.*—Specimen consists of a portion of the stomach about 17 cm. long and 14 cm. wide. The greater part of the stomach wall is studded with polyp-like growths from 0.5 to 2 cm. in diameter. The mucous membrane between these masses is thrown into deep folds. There is an irregular mass about 12 by 6 cm. in diameter, resembling to some extent a bunch of grapes arising from the mucosa on the lesser curvature (?) about 5 cm. from the pyloric orifice. The nodules forming this mass are similar to those coming directly from the mucous membrane.

*Microscopic Examination.*—A section of a large polyp-like mass 1.5 cm. in diameter shows that it is attached to the underlying stomach wall by a pedicle 0.5 cm. across. The muscular coat of the stomach forms a regular layer below the polyp. The polyp consists of greatly hypertrophied mucous membrane, the muscularis mucosa and a loose connective-tissue core continuous with the submucosa and containing fairly large arteries and veins. The muscularis mucosa can be traced as a thick, doubtless hypertrophied layer at the base of the mucous membrane separating it from the core derived from the submucosa. On section the polyp exhibits three lobules, each of which contains an extension of the core, here consisting of connective tissue and muscularis mucosa. The hypertrophied mucous membrane which forms the main mass of the polyp consists of immensely hypertrophied glands, often with irregularly widely dilated lumina. Near the surface the dilatation and irregularity of the glands is greater than that deeper down. Here the gland consists of unusually high columnar cells with nuclei near the base. A very large portion of the cells have the characters of goblet-cells and are obviously secreting mucus in large quantity into the dilated lumen of the gland. At the base of the mucosa in contact with the connective-tissue core, small glands resembling the pyloric glands of the stomach are abundant. The interstitial tissue between the glands contains cells in great number. These are in part lymphoid cells, in greater part plasma cells; eosinophils occur in immense number throughout the tissue, and polynuclear leukocytes in places are fairly abundant. The connective tissue forming the core of the polyp is the site of acute inflammation. Polynuclear leukocytes occur in large numbers and scattered among them in much smaller number are eosinophil cells.

Section through the stomach wall near the pylorus at a point where the mu membrane is greatly thickened, although there is no

trophy and dilatation of the glands, inflammatory changes in the mucous membrane, hypertrophy of the muscularis mucosa, hemorrhage into the submucosa probably traumatic, and hypertrophy of the mucosa.

At the base of the mucosa are a number of widely dilated glands having the appearance of small cysts. The interstitial tissue of the mucosa contains an immense number of plasma cells, among which eosinophil cells are thickly scattered. Lymphoid and plasma-cells form collections of considerable size, particularly below the surface of the mucous membrane. The submucosa shows a mild inflammatory reaction containing scattered polynuclear leukocytes and eosinophil cells.

A section from the cardiac end of the stomach shows no hypertrophy of the mucous membrane. The glands appear to be displaced in part by accumulations of cells in the interstitial tissue which are most abundant immediately below the surface. Here lymphoid and plasma-cells are collected in immense number. Eosinophil cells are very abundant and form in places conspicuous collections. Parietal cells occur in scant number. Several cysts of small size occur and in some of these polynuclear leukocytes are fairly abundant.

The lesion corresponds with what is described as gastritis polyposa.

There is throughout the stomach both within the substance of the polyp and elsewhere evidence of chronic gastritis in marked degree. The relation of polyp formation to gastritis cannot be defined with certainty. On the one hand, the polyp may be regarded as a hypertrophy of the mucous membrane brought about by irritation associated with inflammation. On the other hand, the polyp may be regarded as a tumor or adenoma formed by proliferation of the glandular tissue. Localized hypertrophy of the mucous membrane will lead to the formation of the pedunculated polyp, the connective-tissue core being mechanically drawn into the nodule.

## CONCLUSIONS

1. Though the diagnosis was made possible in this case through the presence of a small polyp in the wash-water during lavage, which also occurred in Chosrojeff's case, and the presence of a large polyp in the feces following the hemorrhage, it would seem that at least a probable diagnosis might be made in future cases without this conclusive finding.

2. The roentgenographic and fluoroscopic examinations in a case as extensive as this should always be helpful. I have not seen a similar picture in other conditions in my own experience, or in the records presented by others. The mottled appearance of the entire right half of the stomach, as though the bismuth were trickling through and around numerous masses, together with the irregular and indefinite outline of the stomach, could be produced only by such a condition as here described, or a most extensive malignant disease which would readily be differentiated by other means.

3. Achylia gastrica, also observed in Wegele's and Chosrojeff's cases, together with unusual mucus production (Chosrojeff), should always arouse suspicion. Ordinarly in achylia gastrica mucus is not encountered in the wash-water either in the large quantities here described or with the peculiar egg-white character, such as one would expect in the great multiplication of goblet-cells.

4. The repeated presence of fresh blood microscopically in gastric contents removed with care, or in the wash-water, is indicative of a redundant, vulnerable condition of the mucosa in which bits of tissue are readily removed by the tube. I have observed this more often in chronic gastritis than in circumscribed lesions such as ulcer or carcinoma. This should at least lead one to think of the possibility of polyposis. In this case, as in those of Wegele and of Chosrojeff, the clinical picture was that of a chronic catarrhal gastritis, with, perhaps,

fewer symptoms than are ordinarily manifested by gastritis patients.

5. In severe, acute, gastric hemorrhage in a patient with achylia gastrica, abnormal mucous production and normal or increased gastric motility, polyposis is more than probable.

6. Invagination of the pylorus by a polyp could hardly be mistaken for any other condition, after one has experienced the peculiar palpatory findings described in this case.

7. The etiology, of course, is very obscure, but it would seem probable that syphilitic gastritis was here the underlying cause.

Wall Building.

# GROWTH AND EFFICIENCY OF HOSPITALS *

H. B. HOWARD, M.D.
BOSTON

My excuse for taking up any of your time is that I am appointed chairman of this section, and it seems to be one of the duties of the chairman to open the session with a few remarks. I can assure you that nothing that is of interest to general hospitals is foreign to my sympathy.

This section was formed, as most of you know, last year, and if its work shall prove to be of benefit to the general hospitals, it will grow and have its excuse for existing.

The general hospital is becoming an important factor in most communities, not only of this country, but also of the civilized world. It is almost startling to see what has been accomplished in the multiplication of these hospitals during the last few years.

The first hospitals in this country were the New York Hospital, the Pennsylvania Hospital and the Massachusetts General Hospital. It was nearly two centuries after the first white man landed on the shores of Massachusetts Bay that the first of these was built. The Massachusetts General Hospital was the third. Although the corporation was formed in 1811, the building was not ready to receive its first patient until 1820.

Few municipalities of any size now exist without their city hospitals. If there is not a city hospital, you will find a large private institution within its confines that is devoted to the public interest. I believe that it is not an exaggeration to say that there are twice as many hospitals in existence to-day as there were three years ago. If this is thought to be an exaggeration, you will be convinced to the contrary by talking with some of the firms that make equipment for general hospitals. You will find that all of these firms have been so loaded down with orders for equipment during the last three years that it has been impossible to keep pace with them. This being the condition, it is fortunate that the American Medical Association has formed a section that is devoted to this subject alone.

With this rapid growth, many of the hospitals are undoubtedly in a more or less crude condition, and meetings of this kind tend to perfect, refine and develop those that have been hastily constructed and perhaps carelessly organized into more healthy and common-sense institutions. No hospital can hope to grow in size or reputation unless it has a well-organized staff and keeps the interests of its patients well in the foreground.

Too much cannot be said, and too much emphasis cannot be placed, on treating the applicants for admission to the hospital in the most dignified, gentle and courteous manner. It should be part of the education which the hospital owes to the community to impress all who knock at its doors with its sympathy and kindness toward them and their maladies. I know that it is a hard thing when you cannot accept patients and relieve them, so to conduct yourself toward them that they realize that you regret your inability to be of service to them; but this is one of the vital points to be insisted on at the very outset when any hospital throws open its doors to the public.

The care of the patient may be prompt, may be scientific and may be most effective, but a hospital will grow slowly in reputation if its promptness and efficiency in treatment and diagnosis are not carried forward with an attitude of perfect courtesy toward its patients.

The three things that our hospitals should stand for are (1) the care of the patients, (2) scientific investigation and (3) the education of physicians, nurses, orderlies, every one within its walls, and through them the community at large, concerning the various maladies that are brought within its doors.

I can well remember, when I was a student visiting the outpatient departments in the city of Boston, being impressed with the helplessness of the physician to relieve the various patients that applied. At that time there was not so much thought taken, or so much effort made, to give advice that the patient was able to carry out. A patient who after a careful examination was found to have tuberculosis was given the prescription, emulsion of cod-liver oil and told to spend his winters in the South. The fact that a man was a day-laborer and had a large family dependent on him for support and not a dollar at his command for traveling to the South apparently did not have much effect on the physician. I have seen a patient without a cent in his pocket loaded down with prescriptions which would have cost him two or three dollars to have filled.

When one of these patients applies to-day at our outpatient departments, first, a careful physical examination is made and conditions are noted; then, there is an investigation as to his ability to apply the treatment. Someone visits his home to see if it is possible for the patient to sleep outdoors. If it is not, some society produces him a sleeping-porch. If he cannot pay for the medicines that are needed, the hospital, as a rule, furnishes these medicines free. If he needs a few months in a tuberculosis sanatorium to begin with, this is provided for, and a social worker interests the various charitable organizations to look out for the family during this sojourn. When he is returned to the community, the same careful investigation is followed up. He is gathered into a class of tuberculous patients who meet evenings to get their directions and encouragement from the physician. So that in a short time this family and the neighbors have all become educated in what it is proper to do, not only to help a tuberculous patient to recover, but also to prevent others in the neighborhood from contracting the disease. The sputum is carefully looked after and destroyed, and the whole family is enlightened as to the dangers of carelessness in the conducting of such a case.

This progress has been made largely, if not entirely, through the hands of the general hospital. I have men-

---

* Chairman's Address before the Section on Hospitals of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

tioned tuberculosis because that is one of the diseases most frequently heard of; but in the average community other conditions are beginning and I may say are well under way, to be handled in the same enlightened manner.

I have mentioned scientific investigation as second in importance. Some of us feel that the people of Massachusetts may fairly be considered up to the average in intelligence. Yet a private hospital, conducted for the public welfare in one of its university towns, tried to start a small laboratory less than twenty years ago and the president of the hospital objected strongly to having such a department within its walls. This president was not an ignorant physician. I have read many of his papers decidedly to my advantage. He had stood well to the front in Massachusetts as one of the leaders, but he gave it out as his dictum that no money should be spent by that corporation in so useless a department, and that if it was insisted on he would resign.

Another hospital in the same state built its laboratory about sixteen years ago, and the chairman of its board of trustees reiterated to me many times that he had no sympathy with spending money for that purpose; that the money raised for the building of this laboratory would have come to the hospital anyway in the course of time for the actual treatment of the patients and doing good to the poor.

It is difficult for us to place ourselves back even this short period and realize the attitude of educated men toward scientific investigation in our hospitals. To-day these hospitals would be laughed at if they were not making honest effort for efficient work in these departments.

The laboratory in each department in many hospitals to-day is many times as large as the laboratory of the whole institution ten years ago, and it is because of this very scientific advancement in the treatment of a case that it becomes necessary not to lose sight of the gentle and sympathetic care of the patient.

There is no longer any fear of not having the support of the community in scientific investigation, provided the interests of the patient are well guarded and the attitude of the staff toward the patient is carefully looked after. We should try to see ourselves as others see us and then make such changes in our attitude and manner as common sense dictates.

I know of a layman who is a trustee of one of the large general hospitals in Massachusetts, who has become convinced that the place for scientific investigation in all medical and surgical matters is in the hospital and not in the medical school; that funds should be solicited for this purpose, and that the scientific work of the hospital should be as heavily endowed as the department for the treatment of patients. He feels that scientific investigation of medical and surgical matters would progress much faster, and in a much more economical manner, if it were divorced from the schools and entirely engrafted on the hospitals themselves. He believes, and supports his belief with plausible argument, which I believe has not been proved unsound, that the medical school should simply be used to teach what the scientific departments of hospitals have proved to be true.

Many a community has a hospital built for it or has money left to it for building a hospital and goes ahead in a blind sort of way to construct an institution which [illegible] for is larger than it needs [illegible] running it. I recall [illegible]

A hospital without patients cannot educate; it cannot do good. If some of the money is used to construct smaller and more economical buildings, and the part which is left is used for opening and running the institution for a few years so that the community becomes impressed with its convenience and usefulness, this education and demonstration, so far as my experience goes, always brings philanthropists to the front who are glad to keep its doors open and furnish it with plenty of funds for legitimate expenses.

The rapid advance in the construction of hospitals makes certain that in no very distant time public opinion will demand that each community shall have sufficient beds in its hospitals to care for every sick person who needs to be within their walls.

The medical profession is gradually being much more carefully educated and much better fitted for the care of patients, but proportionately fewer persons are seeking this profession. I believe that this foreshadows, accompanies and makes for the advancement of the hospital, because the gathering of the sick into hospitals, not only places them where they can be better treated and given a better chance of recovery, thereby lowering the death-rate of the community, but it also conserves the energy of the physician and multiplies his usefulness. Thus far, the physicians may be quite sufficient to handle our sick in a progressive manner, provided the multiplication of the hospitals keeps pace with the needs of the community.

The German communities are much farther advanced in this particular than the American. Their insurance laws have brought about the support of sick laborers and servants in these very hospitals that are built by the cities. The hospitals in the suburbs of Berlin and other German municipalities may well stand as models for cities of much larger size in this country. Pennsylvania, perhaps, is the only state in our Union that has overdone this work.

Three years ago I recommended to the National Hospital Association that we should take steps to have an inspector appointed for general hospitals throughout this country. I still believe that the appointment of a state inspector, better, a national inspector, would be one of the best steps for progress that we could make. He might not please us, but he would help to standardize our hospitals to do away with many abuses that now exist.

I wish to repeat, the first duty of a hospital is the care of its patients. Everything that we do and all the policies that we adopt should be looked at from this point of view: Will this make for better care of our patients?

The care of a patient can never be first-class unless the attitude of the physicians in charge and of the superintendents toward the patient is both kind and sympathetic.

The hospital problem will not be solved until we have enough beds to care for every patient who can be benefited by coming to a hospital.

The hospital conserves the medical energy of the physician, at the same time rendering that energy more efficient. The time is not far distant when this phase of the matter is going gradually to drive all sickness in a community within the walls of a hospital.

The success or failure of these meetings will finally be tested by our success in bringing to a higher and higher standard the hospitals of this country.

97 Huntington Avenue.

# THE SELECTION OF HOSPITAL EMPLOYEES UNDER CIVIL SERVICE RULES*

LEONHARD FELIX FULD
Examiner Municipal Civil Service Commission
NEW YORK

## INTRODUCTION

The underlying principle of the civil service regulations is that the best shall serve the state. The merit system, as it is called, strives to prevent the hospital superintendent from selecting his personal friends for positions in the hospital service and seeks to prevent him also from appointing those who are merely recommended to him by acquaintances. Under the merit system every citizen has a right to file an application whenever a vacancy occurs in a hospital, and the applicant who fulfils in the most satisfactory manner the requirements of the civil service rules is appointed. In this way the state obtains the service not merely of those who may be or may not be efficient, but also of the best available men and women.

## THE COMPETITIVE CLASS

For purposes of administration employees are divided into several classes under the civil service. The most important class is the competitive class. In hospitals this class includes the incumbents of all positions in which substantial salaries are paid. It generally includes all physicians, trained nurses, supervising nurses, chief nurses, trained laboratory assistants, clerks, stenographers and the like. Applicants for positions in the competitive class are required to file a written application for examination. They are then summoned by the civil service commission for a written examination, which usually consists of two parts, one based on technical knowledge and one based on experience. The technical part requires the applicant to submit written answers to technical questions designed to test his possession of the knowledge required for the efficient performance of the duties of the position sought. Physicians are examined in their knowledge of medicine, nurses in their knowledge of nursing and stenographers in their knowledge of stenography and typewriting; their answers are rated on a competitive scale. The experience papers consist of statements prepared by the candidates regarding education and experience. These statements are carefully verified and rated on a competitive scale. Those candidates having the education and past experience best qualifying them, in the opinion of the examiner, for the position sought, receive the highest rating. A properly prepared and properly rated competitive examination in which both technical knowledge and the education and experience of the candidates are rated on a competitive scale undoubtedly results in the selection of the best available men and women for positions for which the hospitals pay a reasonable salary, and for which incumbents are required to have some education and some ability to express themselves in writing.

## THE NON-COMPETITIVE CLASS

The hospitals in this country unfortunately pay many of their employees such small salaries that they are unable to secure men and women who are able and willing to take the examination. Competitive examinations presuppose that there are many applicants for the position. If the hospital must search for the employee it cannot expect the applicant to submit to a competitive examination. In cases of this kind there is no competition between employees for the position, but rather between the hospital and other prospective employers for the employee. In these cases the examination of the applicant is non-competitive. He is examined to determine whether or not he is competent to fulfil the duties of the position rather than to determine whether or not he is the most competent man for the position. Included in this non-competitive class are the domestics, orderlies and other minor employees in the hospital service. The non-competitive examination usually consists of an inquiry into the applicant's personal history, which must in each case be verified. In this connection hospitals seek to give employment with compensation to destitute convalescents, and they also endeavor to bar from their service worthless institutional rounders who fail to perform satisfactory service in any institution. This system of non-competitive examinations is a satisfactory means of preventing hospitals from employing, in minor positions, men and women who are obviously unfit for the positions which they seek.

## THE LABOR CLASS

Positions, the incumbents of which may be efficient, even though illiterate, are in the labor class. This class is divided into two divisions, the subclass of laborers and the subclass of mechanics. Applicants for both subclasses are required to register and are called for examination in accordance with their priority of registration. Applicants in both subclasses are subjected to a physical examination. Mechanics are, in addition, frequently subjected to a qualifying practical test to determine their fitness to perform duties of their trade. It is presumed in the case of laborers that one man in good physical condition is as good a laborer as any other man in good physical condition, and in the case of mechanics that one competent mechanic is as good as another. There is, then, no competition among applicants in the labor class, laborers being subjected only to an examination of their physical condition and mechanics to a practical examination of their competency in their trade. In the hospital service coal-passers, drivers, elevator-operators, ordinary laborers and mechanics constitute the principal employees of this class. This system of selection is reasonably successful in securing for the hospital satisfactory employees of this kind.

## THE EXEMPT CLASS

The exempt class consists of those hospital employees who are not subjected to civil service rules and regulations. This class includes all employees who receive no compensation for their services. Hospital interns and other physicians receiving no compensation are exempt from civil service regulations; but the best hospitals of the country subject all applicants for the position of intern to a rigid written competitive examination of technical knowledge and a careful inspection of personality.

Undergraduate nurses, who receive no compensation, or a nominal compensation, are similarly exempt from civil service regulations. These nurses must possess the preliminary educational qualifications required by statute and are selected by the superintendent of the training-school.

In contagious disease hospitals employees of all kinds are frequently exempt from the civil service rules because of the difficulty of procuring them. The superintendent of the hospital and the superintendent of the training-school are likewise frequently exempt from civil service rule because their administrative duties and responsibilities are so intimately connected with the determination of the administrative policy of the institution that it is deemed best to permit the hospital authorities to select their principal administrative officers without being hampered by civil service rules.

---

* Read in the Section on Hospitals of the American Medical Association, at the Sixty-Fourth Annual Session held at Minneapolis, June, 1913.

### SUGGESTED IMPROVEMENTS

*Personality.*—In the selection of hospital employees by competitive written examination, more attention should be paid to the experience of the candidate, without, however, reducing the severity and thoroughness of the technical examination. Although personality is an important element of the hospital employee's fitness, it cannot properly be made a part of the competitive civil service examination, because the introduction of this element into the examination would tend to introduce an element susceptible of grave abuse. The desired purpose can better be secured by the careful investigation of the experience of each applicant and by derating, and if necessary rejecting, those applicants who have an unsuccessful or an unsatisfactory past record, due in whole or in part to their personality.

*Salaries.*—If the personnel of our hospitals is to be improved better salaries must be paid to the non-professional men and women serving in them. If poor pay is coupled with undesirable service, it is certain that a satisfactory class of employees will not be obtained. The usual reply to this plea for higher salaries is that, since the hospital furnishes maintenance to its non-professional employees, these employees have little opportunity to spend their salaries, and would spend a larger salary, as many of them spend their present smaller salary, principally for purposes which would tend to decrease their efficiency. Although this argument fails to recognize the fact that larger salaries would be likely to attract a better class of men and women, it contains sufficient basis of truth to make us give consideration to the bonus plan, by means of which the employees receive the payment of an appreciable sum of money at the end of their term of service, rather than an increase of salary during their period of service. The payment of a bonus tends to serve as an inducement to permanency of service, and also serves to render less frequent the lapses from a proper mode of life now so frequently attendant on pay-day in public hospitals. The male orderlies are particularly unsatisfactory in this respect. It is believed that, if our hospitals would endeavor to select for the position of orderly men who have been trained by enlistment in the Hospital Corps of the United States Army, they would obtain orderlies who not only possess considerable skill, but who are also men of greater sobriety and readiness and willingness to obey the commands of their superior officers.

*Mechanics.*—In the labor class trade examinations should be more largely introduced as a test of fitness. The complex conditions of modern hospital administration render it more and more unlikely that all men in good physical condition are equally competent and fit to perform the mechanical work of the institution. Simple tests of mechanical skill in the case of almost every employee of the labor class would undoubtedly result in the selection of more competent employees of this class.

*Nurses.*—Under the present system undergraduate nurses are not subjected to civil service examinations at all, because it is presumed that the statutory regulations regarding the educational qualifications and the ability of a competent superintendent of a training-school will accomplish better results than the impersonal machinery of the civil service law. When the superintendent is a thoroughly competent administrative officer this system works reasonably well. As a layman, however, I venture the suggestion that the hospitals are not performing their full duty to the community when they train only the highly skilled nurses who are graduated at the present day. Nurses possessing the preliminary educational qualifications demanded by our statutes and the technical qualifications required of them before graduation from the training-school generally demand a fee for their services which the poor man is unable to pay, and which it is a hardship for the man of the middle class to pay. The hospitals should train two classes of attendants for the care of the sick: trained nurses, possessing all the qualifications possessed by trained nurses of the present day, and trained attendants, who lack some of the preliminary educational qualifications and some of the higher technical skill of the trained nurse. In this way they could furnish attendants who have been trained in a hospital and who could do much to improve the condition of those members of the community who, when sick, are unable to command the services of a trained nurse. During their course of training in the hospital, these attendants will be able to assist the trained nurses; and, after their graduation, they will be able to extend the benefit of trained attendance on the sick to those who are wholly unable, or unable without serious hardship, to employ and pay the regular trained nurse.

---

### ABSTRACT OF DISCUSSION

Dr. Moses Collins, Denver: In many hospitals suitable and sufficient accommodations are not made for this middle class of our community, which is the largest class and which is the best class in every particular. These people most frequently say they are paupers or they cannot get accommodations. If hospital treatment is the proper thing, and we all believe that it is, some radical steps ought to be taken to meet the demands of people who require our services and need the hospitals and whose ability to pay ought to be met in accordance with their means. There must be some provision made for nurses and they must be the best. I do not agree that we should turn out half-educated nurses to take care of the best class of people in the community and that we should give the paupers the best we have.

Dr. Joseph B. Howland, Boston: Dr. Fuld mentioned the possibility of the bonus system. That never appealed to me. As an example of how it does not work, we recently had a strike of telephone operators in Boston, involving several thousand operators. The company fought the best they could, but as they had to give in, one of the things they suggested giving the operators was a bonus at the end of the year. I am glad to say that the operators rejected the offer. I think any attempt of employers to hold their employees over a period by offering a reward at the end of that time is wrong. I think the pay should be on the basis of what a man earns as he goes along. We all like to keep employees a year, two years and five years if we can, but I think that the bonus is not going to go far in solving our problem.

Dr. Moses Collins, Denver: I tried that method myself once in trying to hold interns and similar employees by agreeing to pay a lump sum at the end of a certain term of service. It did not prove satisfactory at all, and after talking with them and asking what they preferred, they said that they wanted their money every month and I have had no trouble since.

Dr. John N. E. Brown, Detroit: Those of us who have had to deal with hospital employees know the great difficulty, first of all, of securing the right sort; secondly, of obtaining an efficient amount of work from them, and thirdly, of keeping them in our employment. It appears to me that we would do well if we could induce our boards to agree to have some place or make some provision for those employees when they leave the service of the hospital. I think, too, that provisions should be made for the employment of married people in certain of the departments. That would tend toward steadiness and keep employees in the service. Besides, they should be well paid, well housed and well fed. It would be much better if we could have buildings especially for them in which we would not need to put more than one, or at most two, in a room. If we would seek to pay our employees well, make good provision for them while we have them and, at the end of their term of service, if possible, have a farm or some place where we could send them and maintain them for the rest of their days or give them an annuity it would tend to give the hospitals and the community at large a much better service.

Dr. John A. Hornsby, Chicago: Some years ago the other large hospitals of Chicago complained to my board of directors that I was disorganizing conditions of employment for other hospitals because I was paying from three to five dollars a month more for wages than they were. My excuse was that I wanted the best and I could afford none other than the best and that in order to get them I would have to pay for them. I did that, but I did not seem to get any of the best of it and after a while I concluded that something else was wrong. So about that time we moved our nurses into a new home and concluded to fix up a building for the female help. I have never been able to do anything with employees except to pay them wages, and never have had the same wages in the same hospital for the same class of employment at any time. We have in our hospital now orderlies who are getting twenty-five dollars a month, and men who are doing precisely the same service who are getting fifty dollars a month. They are living in the house and under exactly the same conditions of employment, but in the one case a fifty dollar man has been there for years, knows the technic of the institution, and has proved honest and will do four times the work of the other man and do it four times better. I have never had any trouble satisfying the twenty-five dollar man that it was a fair deal and that he could get his fifty dollars too whenever he earned it. It seems to me that only by that sort of competition can we get hospital help. I have not had good luck with orderlies from the United States Army.

Miss Harriet S. Hartry, Minneapolis: We thought of a plan some four or five years ago of increasing the wage of an employee if he stayed one year; also giving that employee two weeks' vacation under pay. We have a houseman who has been with us two years, and this year we increased his salary five dollars and he remarked that he would never go away. We have a home for female employees outside of the hospital grounds.

Dr. H. B. Howard, Boston: The civil service rule presupposes that there are a great many people who wish the positions; that is, that there is a waiting list. As a matter of fact, if you have civil service examinations when there is not a long waiting list, it will hamper you terribly in filling your positions.

---

**A Thought for the Aged.**—A cheering thought as we advance in life is that many illustrious examples show the possibility of conserving the intellectual and moral character to a great age. Isaac D'Israeli said that there has been no old age for *many men of genius*. Titian and Michael Angelo among artists, Voltaire and Littré, Goethe and von Ranke among literary men, Palmerston, Thiers, Beaconsfield and Gladstone among statesmen, Wilks and Paget in the medical profession, testify to this, and there is reason to believe that not only is advanced *age consistent* with mental activity of a high order, but that such mental activity tends to the preservation of the body and makes for happiness as well as for longevity. The advice of Cicero is sound, that "old men of all things should especially be careful not to languish out their days in unprofitable idleness"—Saundby: *Old Age*.

# FACTORS INFLUENCING HOSPITAL COSTS *

THOMAS HOWELL, M.D.
Superintendent, New York Hospital
NEW YORK

The question which I am asked to discuss is this: "Why is it that, while hospitals are slowly but surely establishing certain standards of excellence and are attaching to these standards certain specific uses and pretty well-defined prices as to cost, and in this way are approaching uniformity in the cost of institutional maintenance, there is such a wide difference in the per diem cost as there is at present—one dollar per day in some hospitals and three dollars and more in others."

Before proceeding to discuss this question I think that we should have a clear understanding as to what the average cost per patient per day actually means, as printed in the annual reports of the hospitals. It is not computed after the methods which factories employ in ascertaining the cost of their products. The great difference between factory costs and hospital costs is that hospitals make no charge for investments in buildings and grounds or for depreciation of plant.

As the per capita costs published by hospitals represent merely the operating costs and do not take into consideration investment in grounds, buildings and equipment, or depreciation, it is apparent that, while these figures may be of use for comparative purposes, they do not represent the actual costs. If the omitted items were included it would be shown that the actual daily average cost is from 50 to 75 per cent. greater than the published one. The hospital which has a published cost of $2.60 per day would be found to have an actual cost of $4.50 a day. In other words, the average cost per patient per day as computed by hospitals is in reality only about 60 per cent. of the true cost.

The hospitals which I am asked to discuss, one with an operating cost of one dollar a day and the other of three dollars, represent the two extremes. The one dollar a day hospital represents the so-called city hospitals operated generally in connection with almshouses and restricted by parsimonious city governments to small annual appropriations. It goes without saying that in most of these hospitals the features characteristic of almshouses are likely to prevail. The hospital with the average cost of three dollars a day or more, represents a very restricted class of wealthy hospitals in which the practicing of economy is not so essential as it is with the average run of American hospitals. These two classes of hospitals are in no wise comparable and not being representative they may be omitted from this discussion.

Taking representative hospitals, we shall find that the hospitals operated by cities and also a fairly large percentage of those privately operated have costs per patient per day of from $1.25 to $2.00, while other hospitals, also mostly private ones, will have costs of from $2.00 to $2.75 a day. These are the two typical classes of hospitals. Both are well managed; both are doing good work, and to the superficial observer there is no apparent reason why it should require $2.50 a day to care for a patient in one and only $1.50 a day in the other.

Anyone visiting these institutions will be struck with the similarity of the buildings and equipment. Their furnishings are almost identical. There are the same white iron beds, the same nickel-plated sterilizers, the same instrument cabinets, the same operating-tables, the same wheel stretchers and about the same kitchen, engine and laundry equipment. In other words, hospital equipment is pretty well standardized.

---

* Read in the Section on Hospitals of the American Medical Association, at the Sixty-Fourth Annual Session held at Minneapolis, June, 1913.

The initial cost of equipment is probably somewhat greater in the $2.50 a day hospital, but as equipment does not have to be renewed annually it does not figure appreciably in the operating cost.

What, then, are the factors which do influence the average cost per patient per day? I should enumerate them as follows: location of the institution, amount of scientific work done, number of employees and salaries paid, medical school connection, proportion of private room patients to ward patients, service rendered, including food, attendance, etc.

### LOCATION

In think it will be conceded that the environment of an institution will to a considerable extent determine its expenses. The hospital located in a large city where standards are high will cost more to maintain than one in a small city, just as it costs the average family more to live in the big cities than it costs in the small cities or the country.

Life in great cities is complex. All sorts of complications tend to increase the costs. These affect the hospitals.

The standards maintained by the leading hospitals of a city determine to a large extent the standards of their sister institutions. The former set the pace. The others cannot afford to lag too far behind. The weaker ones must progress if they wish to maintain their reputations, and they must maintain their reputations in order to obtain support.

These things affect the municipal as well as the private hospitals. I think it will be found that municipal hospitals in large cities are likely to have a much higher per capita cost than do municipal hospitals in small cities. In fact, their cost is frequently higher than that of privately operated hospitals in small cities.

The per diem cost in Bellevue and its allied hospitals, Fordham, Harlem and Gouverneur, vary from $1.70 to $2.30 per patient per day.

Hospitals located in the South, other things being equal, should have lower costs than those located in the North. Ordinarily food and labor are cheaper in their locality and their expenditures for coal are much less. It costs the Winnipeg General Hospital, for example, over twenty-eight cents per patient per day for coal while the Charity Hospital of New Orleans spends less than three cents per patient per day for this item.

### EMPLOYEES AND SALARIES

I think it will be found that the pay-rolls of hospitals are the most influential factor in determining the average cost per patient per day. The hospital with a small average cost will be found to be operating with few employees and perhaps paying them small wages. The hospital with the high per capita cost will be found to have a larger number of employees and to pay better wages.

In the institution with the low per capita cost the proportion of employees to patients is about two employees to three patients, whereas, in the institution with the large cost the proportion will be about three employees to two patients.

I know of institutions with 250 beds with pay-rolls of from $3,500 to $4,000 a month, and I know of other institutions with the same bed capacity with pay-rolls of from $10,000 to $12,000 per month. In other words, one class of hospital pays out in salaries and wages about fifty cents per patient per day, and the other about $1.20 per patient per day. These are representative well-managed American institutions.

I know of other institutions in which the cost per patient per day for salaries and wages is twenty-eight cents, which is too low, and of others in which it is $1.50, which is too high.

Municipal hospitals outside of the large cities are quite likely to have small pay-rolls. One reason for this is that the annual appropriation by the city government is kept down to the smallest possible amount. Another reason is that certain city officials and their clerks do, without cost to the hospital, work that private hospitals must pay for. For instance, the city treasurer handles the hospital's money, the city auditor audits its accounts and does part of its bookkeeping, the city collector collects its bills and the police department operates its ambulance system.

The hospital with a cost of $1.20 per patient per day for salaries and wages will give to its patients better service than does the hospital with a cost per patient per day of only forty-five or fifty cents. It will employ more nurses and more orderlies and its housekeeping will be better done. It will employ a competent chef and serve better food. It will maintain first-class pathologic, hydrotherapeutic, social service, Roentgen-ray and ambulance departments. It will furnish first-class telephone, front door, clerical and elevator service day and night. It will employ skilled mechanics and its up-keep will be so excellent that depreciation of the plant will not be appreciable.

It is generally recognized that the structural conditions of a hospital plant are a big factor in determining operating expense. A modern hospital built with reference to convenience and economy of operation will be much less expensive to maintain than one occupying old, poorly planned buildings.

Many hospitals have been built piecemeal. The result is a hodge podge, inconvenient to administer and requiring an excessive number of employees.

### SCIENTIFIC WORK

Hospitals which do high-class scientific and educational work are bound to have higher costs than those institutions which do only routine clinical work. They will have a large paid staff doing laboratory and research work. A large intern staff will be necessary, and probably a number of paid, resident-staff men will be employed. All of these men will be furnished with board and lodging, and the salaries paid the men in the pathologic, bacteriologic, chemical and Roentgen-ray laboratories, and those paid the salaried resident staff doing clinical work will amount to a considerable sum. The outlay for laboratory supplies and instruments of precision will influence somewhat the per capita cost.

Hospitals having a reputation for doing high-class scientific work are likely to enjoy the confidence of the public to such an extent that they will have, from a medical point of view, a more important class of cases. The urgent demand on the part of patients for beds in these institutions will result in convalescent patients being discharged early to make room for the more critically ill. The beds will be kept filled with acute cases. Patients suffering with serious or obscure diseases cost more to care for than patients suffering with minor disorders. They require much more care and attention from doctors and nurses.

In the other class of hospitals in which the demand for beds is not so great many of the patients are afflicted with diseases of a more or less chronic nature, are allowed to remain in the institution for long periods, and, in a sense, are little more than boarders and make small demands on the nursing and medical staffs. Patients of this class require much less in many other ways than do acute cases. For instance, they require little laundry work as compared with acute cases. Hospitals catering to this class will get along with about one-half as many laundry employees, and the linen not being washed so often lasts much longer. Neither do these patients require such varied and expensive diets as do those acutely ill. Numerous other items of expense are similarly influenced.

### AFFILIATION OF HOSPITALS WITH MEDICAL SCHOOLS

The hospital which is connected with a medical school usually does more for its patients than does the hospital without such connections, and this results in increased cost. I have no statistics of American hospitals covering this point, but the average cost per bed occupied throughout the year in the London hospitals connected with medical schools is about $600, and in those without medical schools $550.

### PRIVATE ROOM SERVICE

The larger the proportion of private room to ward patients the larger will be the average cost per patient, as the cost of caring for a private room patient is usually double the cost of caring for a ward patient. This is one reason why municipal hospitals generally have a lower per capita cost as, ordinarily, they have no accomodations for private patients.

A number of hospitals provide paid resident staffs for their private service, thus materially increasing their pay-rolls.

There is a general belief that large institutions should have lower per capita costs than small ones. As a matter of fact, it does not work out this way in practice. The big institutions are generally conducted on broader lines than are the small ones; they have more varied activities. While they buy in larger quantities and are thus enabled to obtain somewhat better prices, it is much more difficult for them to enforce economies and to prevent waste. In the small institutions the superintendent is able personally to supervise most of the details and to enforce frugality in the use of hospital supplies. In the large institutions responsibility is divided. And as economy in purchasing supplies does not influence the per capita cost nearly so much as economy in using supplies the smaller hospitals usually have lower costs.

Some hospital officials assert that their physicians are extravagant and attempt to explain their high per capita costs in this way. This accusation ordinarily is unjust and not borne out by the facts. A study of the expenditures of a number of hospitals with a per capita cost of about $1.50 a day showed an average cost per patient per day for medical and surgical supplies of fifteen cents, while an equal number of hospitals with a per capita cost of $2.50 a day showed an average cost of nineteen cents per patient per day for these items. In other words, the hospitals with the higher per capita costs spent only four cents more per patient per day for medical and surgical supplies, leaving ninety-six cents of their excess cost to be otherwise accounted for.

The question has been raised as to whether or not it is practicable to standardize hospital costs. It seems to me that any attempt to do so must meet with failure. I can understand how the costs of individual institutions can be standardized, but I cannot understand how it is possible to apply cost standardization to hospitals as a body in view of the fact that the work done by them and the conditions surrounding them vary so greatly. It would be just as reasonable to attempt to standardize the costs of two watch factories, one of which is producing a fifty dollar watch, and the other a one dollar watch.

The wise hospital superintendent will try to obtain a reasonable per capita cost for his particular institution, not so high that it will invite charges of mismanagement and extravagance nor yet so low that it suggests parsimony and inadequate care of patients.

He will not attempt to make the expenditures of his hospital conform closely in all details with those of some other hospital, or group of hospitals, as he will recognize that each institution, owing to its peculiar conditions and the character of the demands made on it, is more or less a law unto itself.

12 West Sixteenth Street.

---

### ABSTRACT OF DISCUSSION

**Dr. Cleveland H. Shutt**, St. Louis: In comparing our public hospitals with those of Europe, I think that the situation has been satisfactorily explained by the statement that the differences are due entirely to the governmental differences of the country. European institutions are controlled by more or less permanent influences; our institutions are subject to fluctuating influences; consequently, we cannot establish standards and feel that they will be maintained indefinitely.

The question of how we are to establish satisfactory permanent systems for municipal institutions ought to be solved by this and other allied societies interested in hospital work. We know of a number of cities which have expended immense sums of money, in some cases millions, for institutions, and the results have not been, to say the least, a source of pride. We know of cities that have spent moderate sums of money and have enjoyed good management for a period of a few years and then they begin to have unsatisfactory results. In only one or two of our American cities has a city institution of great size given continuously satisfactory service. I think that the Boston City Hospital can be cited in particular. This is a situation which ought to be corrected. I do not pretend to have a solution of the problem, but I have thought of a number of points on which I should like to offer suggestions.

The only way that we can obtain permanency of system for our American institutions is by establishing a medical service in them which will be so satisfactory to the people and profession that they will not permit a retrogression.

The essayist outlined a splendid and proper line of executive control, namely, a board of directors or trustees who shall have complete and full control of the institution in every particular—in the selection of superintendents, erection of buildings, purchase of supplies and appointing of all classes of employees, including the medical staff.

After a body of this kind is organized they should first give the best treatment to the patients who come to the institution. How can this be done? I believe it has been worked out with eminent satisfaction in a number of European hospitals, especially in Vienna, Berlin and London. In England the college hospital has proved eminently satisfactory. In Europe the best medical men in the community have charge of sections of public institutions of which they have full charge and for which they are responsible. The chief practically has control of the appointment of his associates and they form a complete and independent organization for each department. There is opportunity for continuous development of good men for the institution and this gives the public the proper confidence in the institution

Some of the best men in every community are willing and anxious to engage in public hospital service, provided they can be assured of permanency of position and freedom of opportunity for scientific advancement.

Every city, of course, has its local conditions. A city which has only one medical college can work out its public hospital organization without much trouble. There may be difficulty in installing the hospital-college plan, because certain medical men may have positions of medical influence and may hesitate, in the beginning, to accept an inferior position, but this is, I think, for the medical profession to consider seriously. I believe that we hospital men should decide what we would like to do, then go before the medical profession stating that we desire their assistance in establishing something which is going to be permanent for them, for us and for the community, stating that it is going to require some sacrifice on their part in the beginning. I believe that medical men will sacrifice willingly, because I have seen a demonstration recently in my own city, in the reorganization of one of the universities there in which the entire faculty resigned. The majority of them could have held their positions without any question, but they simply resigned for the good of the cause. They said to the board of directors, "You gentlemen appoint a new faculty with the idea of securing as good men for the school as the facilities and accommodations will attract."

MR. W. B. STRATTON, Detroit: Just a suggestion on the matter of plumbing in connection with the hospital. I find that the plumbing boards of this country have developed thoroughly along certain lines, but have not as yet taken up the plumbing of hospitals except to put out catalogs and mark "hospital plumbing" on them. "Hospital plumbing" is their ordinary every-day office-building and hotel plumbing picked out as though it would do for a hospital. I would suggest to the surgeons that they try to think out what they consider ideal in the way of fixtures. They will find the plumbing trade ready to meet them.

---

# THE PSYCHOPATHIC HOSPITAL IDEA *

E. E. SOUTHARD, M.D.

BOSTON

Naturally we are still much occupied with preaching the gospel of psychopathic hospitals in America, since, after all, the realization of our long-cherished ideals is extremely recent (Psychopathic Ward of University of Michigan Hospital, 1906; Psychopathic Department of Boston State Hospital, 1912; Phipps Psychiatric Clinic of Johns Hopkins Hospital, Baltimore, 1913). Nor is the foundation work, which led to the establishment of these three somewhat similar but in many ways contrasted institutions, a matter of very ancient history.

To be sure, Griesinger's idea was early implanted in some American minds. My colleague, Dr. D. H. Fuller, has called my attention to Dr. Pliny Earle's utterance[1] of 1867.

> Carbon agglomerated is charcoal. Carbon crystallized is diamond. What charcoal is to the diamond, such I believe, is the psychopathic hospital of the present compared with the psychopathic hospital of the future. . . . When the defects which I have mentioned shall have been thoroughly remedied by a comprehensive curriculum, a complete organization, a perfect systematization, an efficient administration, the charcoal now just ready to begin the process of crystallization will have become the diamond and the world will possess the psychopathic hospital of the future.

The movement which interests us is more modern. I think especially of Mosher's Pavilion F; of the New York Lunacy Commission's Pathological (later Psychiatric) Institute; of the institution of modern clinical laboratories at Danvers and Worcester, Mass., and at the Government Hospital for the Insane, Washington, D. C. Earlier still we must remember Cowles' work of introducing the seminary idea into insane hospitals and of encouraging science of several sorts in their laboratories, of the early Germanizing and later individual stimulation of American psychiatry by Adolf Meyer, of the extraordinary address of S. Weir Mitchell[2] at a meeting not so long ago of the American Medico-Psychological Association which awoke echoes all about. Back of all this the university and modern scientific movement have contributed in ways impossible here to trace.

I embraced the opportunity to speak before the new Section on Hospitals of the American Medical Association because I knew that many, if not most, of its members would be practical men in charge as a rule of general hospitals. From my general hospital experience I know how important are the proper arrangements for the insane in general hospitals, and I wish to urge unconditionally that their superintendents look to it either to give their insane patients proper accommodations within general hospitals or to spend time and energy getting their local communities to establish proper psychopathic hospitals.

Some of the best general hospital superintendents I have ever known have blinked this problem. Most of you are quite cognizant that excited and delirious patients are not getting proper treatment in general hospitals. The excuse for drugging and tying down the excited and delirious in general hospitals is that other patients are prevented from suffering thereby! The justification for chemical and mechanical restraint is therefore the greatest good to the greatest number.

The reply is simple. There is no excuse for not treating the excited and delirious in general hospitals by the methods long since elaborated in hospitals for the insane. These methods—hydrotherapy, special attendance, isolating-rooms and common sense—can all be supplied in general hospitals except hydrotherapy and isolating-rooms. I have no doubt that all will agree that this proper technic of therapy is not applied in more than a handful of general hospitals, if in so many as a handful, in America.

This topic is so much in my mind that I must be given leave to introduce my notion of the varied functions of the psychopathic hospital herewith. I would call especial attention to forthcoming work by Dr. Donald Gregg, who will give a statistical foundation for my statements, discussing the mortality of delirium tremens in general and insane hospitals, in a communication to be presented at the first annual conference of the Psychopathic Hospital in Boston. I beg leave here to quote Gregg's conclusions:

[2] Mitchell, S. Weir: Address before the Fiftieth Annual Meeting of the American Medico-Psychological Association, Philadelphia, 1894; Proc. Am. Med.-Psychol. Assn., 1895, 1.

1. The results of the eliminative treatment of the deliriums with relative freedom and hydrotherapy, and a minimum amount of medication, far excels in effectiveness the usual treatment by restraint and depressant drugs in cases of the symptomatic psychoses, including alcoholism.

2. Every general hospital should be provided with the facilities for treating properly cases of delirium. Such facilities should include isolation wards where quiet is not essential, and continuous bath apparatus for hydrotherapy.

3. The present situation in Boston, where no general or insane hospital is ready to take and adequately care for cases of simple delirium tremens, is one that should be promptly remedied by the establishment of a public hospital properly equipped for the treatment of inebriety.

But, you will ask, how is the problem of delirium tremens the special task of a psychopathic hospital? Surely it is not the major task thereof. Yet I conceive that it will be an important task of every reception hospital constructed on modern lines to indicate by its mortality tables for alcoholics and by ocular demonstrations of its hydrotherapeutic and non-pharmacotherapeutic methods what similar reception units should be accomplishing in general hospitals.

In this connection I shall quote a brief paragraph from my annual report as director of the Psychopathic Hospital in Boston. Although perhaps the modern psychopathic hospital should not have alcoholism as its major task, yet as to the Boston institution:

> It is to be observed that many cases (thirty) which have eventually to be classified as delirium tremens do in some way get admitted to the Psychopathic Hospital. A still larger number of cases (fifty-four) of the allied disease, alcoholic hallucinosis, are admitted under the temporary care law. The latter, or hallucinosis group, is not specifically excluded by law (as is the delirium tremens group) from admission. It is probably true that the Psychopathic Hospital is somewhat better able to take care of both of these groups of cases than any other local institution, but it is also true that these cases are taken care of at the expense of the non-alcoholic insane, occupying the beds of persons falling more strictly under the authority of the State Board of Insanity. Common humanity and mistaken diagnoses account for most of our admissions of delirium tremens cases. It would seem that a Boston branch of the state hospital for dipsomaniacs should be strongly considered by the proper authorities, and that not only the delirium tremens cases, but many other somewhat curable cases of alcoholic psychosis might well be classified at such a branch.

It is well known that the whole question whether there should or should not be special hospitals for dipsomaniacs cannot be regarded as settled, for the whole country at all events. It will remain the task of numerous, nay the great majority of, general hospitals, to take charge of the acute alcoholics of the community. To do this adequately, the majority of such hospitals will need extensions and new hydrotherapeutic arrangements.

I have plunged *in medias res* by stating to you the mission of the Boston Psychopathic Hospital, which should occupy us for some years, namely that of demonstrating some pretty well-known truths concerning the treatment of delirium, whether delirium tremens or other forms. There is, however, a possibility of novelty for us in this field, as some forthcoming work by H. M. Adler, Chief of Staff of the Psychopathic Hospital, will show. He has secured a quantitative record in the red blood-cell count of the effects in reducing the count in certain cyanotic patients by means of prolonged baths. In certain instances he has been able to predict the probability of an excitement in a patient by the observation of oncoming cyanosis.

What are the major problems of a psychopathic hospital? I have perhaps indicated to you that I feel that they are largely, or at all events extensively, somatic in character, yet a review of the communications to be read on the occasion of the first annual conference of the Psychopathic Hospital in Boston, to be held June 24, 1913, will demonstrate that these problems are much wider in scope than those with which I have before dealt too much *in extenso*.

In the first place, let me insist that far too little stress has been laid in this country on sociologic and psychologic matters in their relation to medicine. In a recent analysis of papers produced by officers in the state institutions for the insane in Massachuetts, I found 43 papers dealing with structural changes in the nervous system, 15 papers dealing with somatic non-nervous changes, 12 dealing with general considerations, 11 dealing with strictly clinical considerations and 7 dealing with psychologic matters. It is clear that such a distribution of interests is by no means a natural one. I found that a fair distribution of interests in our first annual conference divided the medical and social results of our first year's work into about equal parts, from which I conclude that the outpatient and social service relations of a psychopathic hospital must be among its most important functions.

I shall dismiss the remainder of my discussion in brief paragraphs, although I know that each of the main topics would require a discussion somewhat similar to that which I have given of our mission with respect to delirium.

We have at least as important a mission with respect to syphilis. When the patients admitted to a state institution for the insane show positive Wassermann reactions in 22 per cent. (H. L. Paine's data, Danvers State Hospital), or, as at times for certain months at the Psychopathic Hospital, from 25 to 30 per cent., it is high time that social workers and economists as well as physicians should begin to take an interest in that field of mental hygiene which shall seek cooperation with the sex hygiene propagandists. Two features of the syphilis situation have struck me during the last year. In the first place, Dr. W. P. Lucas has shown the great importance of syphilis in the children and adolescents coming to the Psychopathic Hospital outpatient department. The percentages are by no means final, but arrest attention. The relation of syphilis to specialized defect of the mind, coupled with defect in auditory imagery, has also received attention in our examining-rooms. It has been possible to advocate special educative measures in certain cases with specialized auditory defect in imagery. Auditory defect in imagery has been shown to be much more common than visual defect in imagery. Certain backward children, as a result of Dr. Anderson's work, can be given specific visual instruction to replace the auditory type used in many schools. The problem of certain "terrors" in school may thus be partially met.

In the second place, the novel suggestions of Dr. Homer Swift of the Rockefeller Institute give opportunity to optimistic therapeutics in the field of general paresis and other forms of cerebrospinal syphilis.

Here is a field in which a psychopathic hospital can work far better than the state institution of older style, since many hands, medical, nursing and technical, are at hand in a psychopathic hospital equipped for the pursuit of general medicine.

With these inadequate words I leave the topic of syphilis in a psychopathic hospital; but of course, syphilis is a problem which is in many ways transmedical and will require the cooperation of social workers and economists to the last degree if we are ever to "scotch the snake."

I have studied the social service movement with a great deal of interest and have made many friends among the social workers. There is a new but growing sense of the value of social work, and the accompanying sense of pride on the part of the social workers themselves is much in evidence. For this I do not blame the social workers, but we must all fear that the well-known spiritual pride of physicians meeting this now as yet uncertainly founded pride of the social workers will forbid the best cooperation for some time to come. Perhaps this is particularly true in mental medicine; for alienists have long been social workers in their fashion. They have been more truly economists and social workers than the general practitioners or specialized physicians of our general hospitals, and have been approached only in their economic and social sense by the superintendents of general hospitals. As you know, however, the latter have been recruited in many significant instances from among superintendents of hospitals for the insane, so that the group represented by the Section on Hospitals before which I am now speaking is a group in which the existent sense of social service is perhaps largely derived from long-standing medical contact with psychopaths. The new movement requires cooperation and coordination between physicians and the new lay forms of social service. Progress should be made in every community to determine the dimensions of the social problem as it affects the psychopath. In many states the minor wards, the adult poor and other largely non-psychopathic dependents have been pretty adequately cared for by systems employing lay visitors, investigators and other agents of centralized boards. Social service for psychopaths, except those who are met in the various classes just mentioned, is as yet non-existent in any systematic and well-rounded form. Estimates will be shortly available concerning the dimensions of this problem also. For example, the Psychopathic Hospital Outpatient and House Service in Boston has been shown to demand very probably about eight social workers, and the problem of the rest of the state, should it remain at the present level, could perhaps be covered by seven more. Experience, however, shows that preliminary estimates are, as a rule, too low for this form of work. The leaders in social service do not yet understand adequately the difficulties in social service for psychopaths, having had their minds riveted on problems of investigation, financial and social relief not systematically involving the somewhat less predictable proceedings of the psychopath.

So much for the suggestion of problems being attacked in the modern psychopathic hospital. I have brought into stronger relief the problems of delirium, of syphilis and of social service than others. Nor have I mentioned the more intimate, complex and difficult problems of pathogenesis and etiology in mental disease which the workers attracted to a proper psychopathic hospital will engage in. I had not thought it worth while to present such matters to the section before which I report, and refer my hearers to special contributions elsewhere. Let us hope that American enterprise and imitativeness will far more speedily bring about the dotting of this country with new hospitals, each an advance on its predecessor and, in conformity with the American spirit of autonomy, no one exactly like another. Some say there should be a psychopathic hospital in every city of fifty thousand inhabitants; others say in every city of a hundred thousand inhabitants. Such claims refer, of course, rather to receiving hospitals with an immediate diagnostic and therapeutic aim than to more elaborate institutions of the Ann Arbor, Boston and Baltimore types. The necessity of smaller psychopathic hospitals would be largely removed, should the general hospitals of the cities in question think it worth while to face the problem of the acutely insane of their districts.

Whose fault is the present reign of ignorance as to the proper treatment of the acutely insane? The practitioners in neurology say that they have warned general hospital superintendents concerning their duties with respect to installation of baths, special attendants and isolating-rooms for the delirious. The surgeons and physicians say that these matters are largely in the hands of interns under the present system; and some say that proper residents of longer experience will meet the problem. I am not sure that we can absolve the neurologists and even more the hospital internists from responsibility for the poor treatment which the insane receive in general hospitals. I am certain that an organization like this Section will do much good, for its members can push on the financial side of the problem by providing ways and means for the installation of proper nursing and other external arrangements. To-day is certainly an era of busy interest in sociology. The psychopathic hospital in a community is bound to be one of the most concrete sources of enlightenment as to psychopaths, and every society for mental hygiene, for sex hygiene, for the amelioration of alcoholism, for eugenics, should make it part of its business to help start a psychopathic hospital with its outpatient service in every community in which there is any hope of awakening social sense.

240 Longwood Avenue.

---

## ABSTRACT OF DISCUSSION

**Dr. John A. Hornsby**, Chicago: A week or two ago I was called to account because of a page in my work on hospitals concerning the restraint of patients. I am wondering whether Dr. Southard has run across the same class of cases as we have and what he would do with them. For instance, a patient who has been operated on develops surgical delirium tremens. He begins to yell and fights if you undertake to prevent his yelling. He fights against every sort of restraint. If you let him go to the limits of the room and his surgical injury is such that he can be allowed to go there without danger, then he fights to get outside. What would Dr. Southard do with a patient of that sort?

**Dr. E. E. Southard**, Boston: We cannot treat these cases in the ward of the general hospital as it exists at present. The method of treatment which you have carried on in the general hospital as at present constituted seems to have something to do with other patients in the vicinity. Now we should not be averse to treating a patient after a certain fashion because there are other patients in the vicinity. We should have proper conditions. We should have isolation rooms. We should have wards with safety deposit vault ventilation principles in which noise could be eliminated. I do admit that is really a problem. The general hospital superintendent will have to contrive to have some money spent on modern devices for prevention of noise, prevention of the transmission of noise, so that it will not disturb the neighborhood.

In the next place, if it is an opened peritoneum that the patient might take the sutures from, the restraint is obviously necessary. I suppose no one would deny the importance of keeping the patient's hands out of his peritoneum. However, many of these cases are under a certain amount of depressant treatment anyhow, without resorting to a drug. I take it that that question is hardly a problem of great moment.

But if you have some properly ventilated noise-proof ward in your plant, equipped with modern hydrotherapeutic appliances, you will, I think, reduce a good deal of the violence which characterizes many of the general hospital wards in which I have worked.

According to Kraepelin a delirious or excited patient should not be strapped to the bed. If he does not stay in bed he should be placed in a warm bath of blood heat, and if he will not stay in this bath with gentle persuasion he should be put into a moist, warm pack for a limited period. He is given to understand, if he can understand what is going on, that it is to be for a limited period, an hour or two; he should then be removed and placed in bed. If he will not stay in bed he should be placed once more in the warm bath, and if he will not stay there, once more in the pack. This cycle of bed, bath, pack is repeated ad libitum through the night, if you have the nurses. You can seldom find a superintendent who will give you nurses for this purpose, because they are not to be had. Still this is indicated by the therapy of the patient, and why not do the best for the patient, if you are going to permit him to recover? There is hardly a case of the non-surgical sort in which there is not positive danger of infection of the wound that will fail to be benefited by this simple hydrotherapeutic procedure which Kraepelin has advocated and which has some thirty years of history back of it.

So I say a new type of ward and new hydrotherapeutic measures will meet most of the problems of the delirious patient met in the general hospital. There might be a few, as Dr. Hornsby mentioned, whom we might have to put in the insane hospital.

How many patients of this kind do you think that there are in a year in your hospital, Dr. Hornsby?

Dr. Hornsby: In a hospital of 350 beds, of which I have been in charge, I should say three a week. The percentage of surgery is large. We do in that hospital from twelve to fourteen major surgical operations a day.

Dr. Southard: Well, then it would not cost an extraordinary amount of money to put up a plant like that in the Belfast and London institutions and put in hydrotherapy and treat these cases in that way.

Dr. John A. Hornsby, Chicago: It is not the cost of such an institution in that case, I take it. The cost is in transportation of the patient, especially from the general ward or from the quiet room, to such an institution and the cost to the other patients in such a case.

Dr. Arthur B. Ancker, St. Paul, Minn.: It seems to me that it is not so much a question of the noise, and the consequent disturbance of the other patients, as it is a question of preventing the patient from doing great injury to himself. Not an insignificant proportion of the surgical patients who have developed delirium tremens have wounds that make it important that they should be, as it were, immobilized; in some cases we are told that they must not be allowed to sit up in bed, that there must be no exertion whatever; so even supposing that we had the hydrotherapeutic equipment, in many cases the patients would necessarily be deprived of this treatment because we would be unable to take them from their beds. We, at the hospital, have had many opportunities to consider all these conditions, and, while I believe that the treatment which is most in vogue in general hospitals is not altogether humane or desirable, yet I have seen two or three hundred cases in thirty years and I have rarely seen one in which we did not have to do something in restraint of violence, and I cannot quite understand how, under the circumstances, one could well avoid the use of restraints or the use of drugs or the use of both of them. The police ambulance brings us many victims of long debauches suffering from delirium tremens, probably a couple of hundred a year, and I quite agree with you that the hot pack, hydrotherapy and a sufficient number of nurses are essential for the proper care and treatment of that class of cases, but it is not to that class that I am particularly referring; we have to deal with a condition that complicates not an inconsiderable number of the surgical cases that appears a good deal like delirium tremens; these are the cases that we have to keep in bed, that we cannot put in hot packs, and that we cannot take to the hydrotherapeutic room, even supposing we have one; the kind of a case that leaves us nothing else to do but to use restraint or give some kind of a drug to put the patient to sleep temporarily.

Dr. E. E. Southard: I should like to say a word as to restraint, with respect to the bath-tubs. Really it is not a restraint and those little knobs that one of the plumbing companies puts on the tubs which permit you to tie the patient in ought to be left off.

Dr. Rupert Norton, Baltimore: Suppose you have them in a pack?

Dr. Southard: The pack is a restraint up to a point. The patient, however, as I say, is told at certain times what it is for and, if he understands that, so much the better. If he cannot understand what is going on it goes to restrain him.

There is no psychologic objection to restraining an unconscious person, I think. There is an objection on the part of psychology in this instance because the patients understand, but there would be really no objection, I take it, to restraining an unconscious patient. Of course persuasion is, in a sense, a sort of restraint; you exert a mental effect on the patient. The discussions of Dr. Hornsby and Dr. Norton have led to a description of a small number of delirium cases, whereas what I was talking about was the large group of delirium tremens cases. In almost eight hundred necropsies at the Boston City Hospital about 8 per cent. proved to be really mental cases, chiefly cases of delirium tremens. Now I am quite convinced from the result of these necropsies that a good many of the patients might not have died if proper treatment had been employed. Of course one might say, "What do we want to treat them for? Why not let them die?" That is, however, not humane.

Dr. Cleveland H. Shutt, St. Louis: I believe that most delirium tremens patients can be treated by hydrotherapy, but we know that there are certain cases in which this treatment is impossible. A patient has been shot in the abdomen and it is necessary to place drains in the abdomen in several places. We can use hydrotherapy to a certain degree, if we are enthusiastic in that direction, but we can accomplish most for the patient by using restraint and drugs. Traumatic injuries, complicated by delirium tremens, will also require judicious treatment without frequent transferring from bed to tub, or even placing in water, and risking danger of infection.

Dr. H. B. Howard, Boston: I am convinced that there is more or less ill-advised restraint in our general hospitals. I think that it comes about in this way: A delirium case develops in the night and there is nobody but the house physician and the superintendent there, and if the rules of the hospital are not such that the superintendent has to be called in to each one of these cases, there is no doubt that there is ill-advised restraint applied, because it is applied by the young man who has never had any training in an insane hospital and it is applied in a crude manner.

Dr. George F. Jelly used to say that before you tried restraint you ought to see what light and society will do for your patient. Now we would add to light and society continuous bath.

Dr. E. E. Southard, Boston: I wish that the state board would request the superintendents of general hospitals to obtain a record.

Dr. Howard: If they had any authority over them doubtless they would. I admit that there is a good deal of ill-advised and poor restraint. Perhaps restraint is necessary in a few cases and it can be so applied as to be of little damage.

# HOSPITAL AND ASYLUM WORKSHOPS

## SOME POSSIBILITIES OF HANDICAPPED LABOR *

HERBERT J. HALL, M.D.
MARBLEHEAD, MASS.

It is so hard for well people to make a living that the casual thinker will not believe it possible for sick men to work effectively and without harm. When the invalid is poor we perform but the natural part of charity if we give him medical treatment and save him from the necessity of work. Yet experience has shown that in many chronic illnesses effective and remunerative work may be accomplished with physical and moral benefit to the workers.

The object of this paper is to suggest the possibility of workshops for the chronic invalids who haunt the outpatient departments of the great hospitals and who have collectively a great deal of efficiency and skill, though they cannot find places in the usual fields of labor.

We do not have to search long for suggestive examples of work among handicapped people. The blind have thriving industries, the cripple schools have for a long time been engaged in teaching their pupils trades adapted to severe limitations. One of the most refreshing activities of modern institutional life is to be found in the schools for feeble-minded such as that at Waverly, Mass., where, under Dr. Fernald, there is an effective system manned almost wholly by patients who in the old days would have been idle. In the insane hospitals all over the world the patients are more and more generally given work to do in connection with the farms and households, and lately in workshops like that of Dr. Tuttle at the McLean Hospital in Waverley and at the Hans Schönow under Dr. Laehr in Berlin. Besides all this activity in charitable or semicharitable institutions, there has of late years been a remarkably effective use of modified work as a remedy in the sanatoriums for the treatment of nervous exhaustion among people of means who have overworked and overworried or who are suffering from the effects of too much idleness. These industrial experiments have all been so hopeful in their results, so beneficial to the workers and so surprisingly productive that it seems almost certain that important developments may be expected from outpatient industries.

My own experience has been in sanatorium work with nervously exhausted patients. I have found that among persons of education and taste the ancient handicrafts offer a most interesting and profitable means of regaining strength. I believe that some modification of this crafts-work system will be easily available for hospital shops. With a basis of this kind we should be able to show the therapeutic possibilties of work in a large range of cases. The economic possibilities for hospital patients remain to be proved, but they are decidedly interesting.

Crafts work is a vague term and may be easily misunderstood. It means, generally speaking, work by hand instead of by machine, and it includes almost any useful and ornamental product, from a rug to a coal scuttle. The important difference is that the crafts work at its best is confined to products that can be made better by hand. The world is beginning to appreciate that a great many articles of daily use are best produced in this slow way. It is true that the finest work of the craftsman, the goldsmithery and silversmithery, the wonderful dyes and weaves that make inimitable fabrics, can be done only by highly trained workers. But there is an enormous mass of routine and preparatory work in the crafts, and this work can be done perfectly well by handicapped persons if they are carefully directed and controlled.

Men are thrown out of employment for very trivial reasons—it does not follow that they are good for nothing because they fail to fit the particular job they happened to find available. The new system will gather up these sick and discarded workers and adapt them to work which will be graded and controlled to meet any degree of handicap. There will be some agreeable surprises for those who bring this plan to pass. Many a woman considered unfit by the great industries, many a man injured or worn out by the grind of the factories, will prove to be highly efficient under conditions that are slightly altered to meet the especial need. The wasteful policy of the regular industries may or may not be necessary, but it is likely to necessitate a secondary system of labor. Some day it will be impossible for society to support the number of sick and idle; then the new system will come in earnest.

In their beginning the new workshops will have to be subsidized, for they will count the worker more than the machine and that will mean small returns at first. But there will be few high-salaried officials under the new plan and the profits will go to the workers. That is one of the reasons why such a system may be successful financially in these days of struggling industry.

As I have watched handicapped labor—grateful, loyal labor it usually is—I have been deeply impressed with its possibilities; for I have watched also the slow steps of the dissatisfied and unscrupulous workers in some of the regular industries and I am not sure that the handicapped workers will fall so very far behind.

In any event, the new work must be a great deal more than a plaything. We have no right to ask our handicapped operatives to give their time and strength, even if they improve physically in the process, unless the work is worth while, unless it has a ready market value. That is the final test.

From personal experience with a different class of patients I believe that hospital workshops of varied kinds may become nearly or quite self-supporting. During the past few years I have, as a matter of fact, been able to build up such a business in a small way and a good deal of the time it has been made to pay. This work has been conducted as a private venture with very little outside help.[1] The workers, it is true, have been people of high intelligence and not in need of self-support, but they had given up, they were not able to succeed under ordinary conditions, so the principle is the same. This small business has been under way nine years. During the past four years it has been a little more than self-supporting, although before that it was a decided financial burden.[2] The work has succeeded because we have always had expert workmen guiding and directing at every point. Such shops are, of course, partly professional. I believe that this professional combination must always be followed. Handicapped workers alone are almost surely helpless; working in cooperation with experts they may become a tremendous source of power.

---

* Read in the Section on Hospitals of the American Medical Association, at the Sixty-Fourth Annual Session held at Minneapolis, June, 1913.

[1] Twice within the past nine years I have received a grant of $1,000 from the Proctor fund to assist in the study of chronic diseases.

[2] Owing to enlargement of the plant the workshops have recently failed again to meet expenses.

We have tried hand-weaving, metal-working, wood-carving, leather-working, pottery, basket-weaving, and cement-working. We have dropped all but the pottery, the hand-weaving and the cement-working because we could not see our way to making the others pay.

Last year five persons working in the pottery made and sold six thousand dollars' worth of pottery. Two of these persons were professional potters, one was an apprentice, and two were former patients who because of illness could not meet successfully the conditions of life outside. One of these patients, a woman, had been a surgical patient with profound neurasthenia of long duration. She began her work with little power of sustained effort. The other was a young man so handicapped physically that he might not have been successful even here without medical management. I present this experience simply to show that the idea of using the handicrafts is not altogether impractical.

The money value of handicapped labor has been demonstrated again and again, in institutional life at least. Last summer a small group of men patients at the State Colony in Gardner, Mass., under Dr. La Moure, produced forty thousand dollars' worth of supplies from the hospital farm. That return, at least, would not have materialized without the use of handicapped labor. We hardly need to be assured that the men who worked on that farm were not overworked and that they were physically and mentally better for their experience.

Out on the Pacific coast, Dr. Philip King Brown has within the past two years established a pottery, in which, under expert guidance, a group of convalescent tuberculous girls are paying their expenses—a dollar a day—while they are under sanatorium treatment.

We are beginning to see the possibilities of a principle, which, given systematic application, may change the face of charitable affairs, a principle which may be expected to restore many discouraged and enfeebled workers to full efficiency.

There are many trades and crafts which may be adapted to this purpose. Some of the craftsmen in my shops have been experimenting for the past two years with ornamental cement work as a possible field for hospital shops. We have found, among other things, that practical and beautiful flower-pots and an excellent quality of brick and tile may be made cheaply and expeditiously by people with little strength. We are finding in hand-weaving a field of the most brilliant possibilities. It might be supposed that in these days of machinery, hand-weaving would be a hopeless thing. On the contrary, it is possible to do by hand especial and individual patterns that the power looms would never stop to undertake. There is a ready market for these specialties in weaving and cement.

If possible, we should have some sort of central bureau that can conduct extensive experiments and that can oversee the entire field and help to establish practical workshops where they are most needed. Such a bureau could conduct a normal school for the training of teachers and assistants. A central office would hasten the day of accomplishment by many years. It would save expensive mistakes and might supply materials, designs and formulas, besides answering many puzzling questions which are sure to arise in connection with the technical part of the work and in relation to the effect of occupation on individuals and classes.

There are, of course, pathetic limitations to such a plan and many a willing worker could not succeed; but is evident that a great deal might be accomplished and there ought not to be a long delay in realization.

My suggestion is a definite one—that such workshops as seem most practical be experiementally established in connection with the outpatient service of a few of the general hospitals. In this way we should soon find out in what particular ways employment would supplement the work of the medical and surgical departments. I am sure that the workshops would prove of tremendous value to the social service workers, who are finding it more and more difficult to secure occupation for their charges, and who will tell you without hesitation that vice and crime breed best in idleness.

The plan must not be left to be worked out by enthusiastic, but untrained, people. Such a course would bring delay and discredit on the whole system. Medicine, social service, the crafts and business management, these are the elements that must be brought together if we are to see the best results. I believe that the thing can be easily done and I recommend the matter to your serious attention.

Until the time when this industrial branch of medicine can be taught in a larger and better way, my own little shops at Marblehead are open for demonstration and as a training-school for nurses or craftsmen who wish to go as far as we have gone. It gives me great pleasure to be able to say that the superintendent and trustees of the Massachusetts General Hospital have already seen fit to authorize the establishment of an outpatient industrial department on the lines of the Marblehead workshops. This Massachusetts shop will be in operation within a month, so that it soon will be possible for visiting men to study the principle under actual hospital conditions.

---

# MUNICIPAL HOSPITALS AND THEIR RELATION TO THE COMMUNITY *

RUPERT NORTON, M.D.
Assistant Superintendent, the Johns Hopkins Hospital
BALTIMORE

Speaking broadly it may be said, without fear of contradiction, that the municipal hospitals of this country are a disgrace from almost every point of view and do not serve the purpose they should in any respect. The exceptions can be counted without difficulty on one's fingers. One of the best is the Boston City Hospital, and the worst, considering the city in which it is situated, is the Cook County Hospital of Chicago. Between these two there are hospitals of all grades. The new Bellevue Hospital in New York could in a few years become a noteworthy institution, but there are many conditions which stand in the way of its development along the best lines possible. In Baltimore there is the beginning of an excellent institution. The same may be said of Cincinnati and of some other cities. Throughout the country there are many well-built hospitals, but there their value almost ceases.

Let us stop for a moment to compare these conditions with those which exist in Germany. There the municipal hospitals are the best in the world, and many towns with a population less than that of the American cities I have mentioned have first-class hospitals from every point of view. Recall for an *instant* the famous hospitals in Berlin, Hamburg, Cologne, Düsseldorf, and many others. Why should there be such a difference when America is so wealthy a country? In Germany hospitals are built and managed by experts. First, there is a most careful consideration of the site by hospital and municipal authorities, and, when this is chosen, the greatest care is exercised in drawing the plans for the hospital, a task again performed by an expert. When the hospital is built, its management is entrusted to trained men. The hospitals in all German cities in which there are medical schools are used by the medical schools for instruction and scientific work, and where there are no schools, the best physicians in the town make up the staff of the hospital. In Germany it has long been recognized that the best service is obtained in any hospital by having it associated with a medical school, and, if that is not possible, by at least having the leading medical men of the community in charge. As a result of this broad point of view, the hospitals in Germany lead in almost every way and are the ones to which we all turn for instruction, not only in the practice of medicine, but in hospital construction as well.

---

* Read in the Section on Hospitals of the American Medical Association, at the Sixty-Fourth Annual Session held at Minneapolis, June, 1913.

It is not altogether easy to explain why the Germans have taken this lead, but there are certain fundamental facts which have played their rôle. The scientific mind of the German has led him to work out this problem as he has others and become a master in it. But why should he have given so much attention to hospitals? Because he has recognized what hospitals mean to the welfare of the community. Again, their development has been absolutely free of the evil influences of political parties. In brief, these may be considered the leading reasons for the position of German hospitals at the head of all others. I shall, as I go on, develop some of these thoughts further and show why it is that America is still so far behind.

In Germany hospitals are show places, like schools, opera-houses, and other municipal buildings, while in this country we would seldom take a stranger to see our municipal hospitals, but rather divert his attention to other places more attractive.

It would require too much time to take up the question of municipal hospitals in France, England and elsewhere, and it is not necessary for the purpose of this paper. All I desire to do now is to point out our own deficiencies as compared with the best and try to show how our defects may be remedied and how we may take an equal rank with Germany in this part of our social life.

I stated a moment ago that the German had built his hospitals so perfectly because he saw what they meant to the welfare of the community, and here I think I may well draw your attention for the moment to one of our national traits, one which has its fine as well as its evil side, and that is our carelessness to loss of life. Yearly, through our indifference, our haste and readiness to put up with evils we might easily control, thousands of lives are needlessly lost by death or wasted by illness. We are improving in this respect, but how slowly! This thoughtlessness has led our cities to the poor construction of hospitals and their still worse administration, or to failure altogether in building hospitals. It is this indifference which accounts for the continued pollution of our sources of drinking-water and the constant prevalence, as a result, of typhoid fever, another cause of loss and waste. When we have had hospitals to build, whom have we selected to do this? Often men absolutely incompetent, who know nothing of what a modern hospital should be, and who do not take the trouble to inform themselves. The best architect cannot build a hospital from intuition. The modern hospital is too complicated a structure to be erected without most thorough study, and the best architect will fail unless he associates himself with those who know the inner administration of a hospital. Plans for hospitals have usually been called for from local architects, who have not the fundamental knowledge necessary, or the architect has been appointed because of social or political influence. I shall not lay too much stress on this point, for we all know how few of our municipal hospitals can be compared at all favorably with those of Germany. The new hospital at Cincinnati is an exception and we may well be proud of it. This is largely due to the study of Dr. Christian R. Holmes and the time and devotion he has given to working out and perfecting the plans. There is no reason why from now on our municipal hospitals should not become models of perfection so far as construction goes.

None will deny that many of our failings are due to political conditions in our large cities. The system of political spoils has interfered in every way with municipal undertakings. When money has been secured in one way or another for the building of a hospital, it has often been extravagantly expended, or wasted through incompetence, or stolen by dishonest contractors. As a result, the community did not get what it should have in the way of a building. This, however, was not the final step in the degradation. After the hospital had been built, it was put in charge of a superintendent who knew little or nothing of his duties, through his "pull" or because some politician wanted to find an easy place for an old and worthless henchman. With this start it was quite impossible to secure the services of the best physicians of the community, for the administration being under political influence, the term of service was most insecure, and at the same time the selection of attending physicians and surgeons did not insure the confidence of the public. The final and general result has been that our municipal hospitals are institutions which the public is now generally ashamed of, and it has good reasons to be.

I have sketched hastily the main conditions of our life which have brought about this most unsatisfactory condition. We are a young country, we have not been inclined scientifically until within a short period of time, we have been and are still extremely indifferent to life and we have been for years in the hands of political ringleaders. These are general principles which with but little change can be applied to almost all of our communities, both large and small. Politics, as thought of in the popular way, has been a game and a business in this country and has influenced our communal life in many ways, both for good and evil.

It may now be asked, What can we do to improve conditions? I do not think that this will be found a difficult task. Our communities are awakening to their physical needs and learning that they need not be playthings for a group of dishonest politicians. All that our communities need is education. Each of us needs education along many lines, and it is not surprising that our people, who have up to the present led easy and successful lives, have paid but little attention to their physical ills and discomforts. The easy conditions of the past have changed, however, in the last few years, and living is no longer easy for a large mass of the population, whose needs require careful attention. A successful, happy community is a healthy one. To be healthy, the community must be provided with those conditions which keep it from being sick and which take care of it when it is sick. The first and foremost requirement to this end is abundance of pure drinking-water, and the second is one or more hospitals.

How many hospitals does a community need? This, of course, depends somewhat on the size of the community, but not altogether, for certain ailments will appear in every community. Where there are children, we shall have the contagious diseases of childhood, and these diseases cannot be cared for in the same building with other non-contagious or non-infectious diseases. In larger cities, the needs of hospitals for various diseases or classes of patients increases; while generally these might be on the same plot of ground, yet it would not always be wise so to construct them.

In a large city there is need of a general hospital for acute medical and surgical cases; one for chronic cases, both medical and surgical; one for contagious diseases, including syphilis and gonorrhea; one for tuberculosis, and one for insane patients. For all of these there should be outside the city at no great distance convalescent homes. I do not think it is worth while in this paper to attempt to draw up any scheme as to the number of beds required, or how a hospital or hospitals of this kind should be constructed. I wish merely to make plain what the needs of a large community are, and what the duties of the community to itself are. It must care for its sick and it should care for them in the best way possible. A patient cannot be given too good care. The quicker he gets well, the greater the saving in the cost to the community. Health means wealth, and a community can well afford to spend sums to prevent illness; sums which seem insignificant when compared to the endless cost of caring for its sick. In caring for its sick, one of the first duties, if not the first duty, of a community is to see that its hospitals fulfill their end, and it should construct them with as much interest and thought as it does its schools, court-houses and city halls. It is not worth while to build expensive schoolhouses if you have sickly children to send to school; and simpler and smaller court-houses would be needed if the health of the community were good, for there would be less crime, and, to go one step further, the greater the health of the community, the less the need of many hospitals. As I mentioned before, the hospitals of a community should be so built as to be attractive, not only to visitors, as that is of comparatively little importance, but also to the sick within their walls.

Too little attention has frequently been paid to certain of the most important parts of municipal hospitals. Not alone the wards but also the kitchen, laundry, boiler and electric-light plants should be hygienically constructed. Too often the kitchen is dirty, ill built and ill placed and entirely lacking in that attractiveness which it should possess. This is also true of the other departments mentioned. In the construction of the hospital it apparently has not been considered necessary to give these dependencies their proper attention, almost all of the money having been put into the wards; but even so, the ward lavatories and water-closets are seldom what they ought to be. They are too small and are usually ill ventilated. On the good planning of the kitchen, laundry, dining-rooms and other quarters for the help depends much of the success and efficient and economical administration of the hospital. The quarters for the nurses also should be airy and comfortable; the nurses should not be housed in overcrowded rooms, badly ventilated and heated. Without giving thought to all of these points and many others in the construction of municipal hospitals it is impossible to secure a first-class institution.

What hospital in this country has thought of disinfecting the water flowing from the necropsy-room, or still more, the waste water of the hospital? This is done in some of the newer institutions in Germany and should be done in all American hospitals if there is danger of the drinking-water of the community being polluted; and where in America does this danger not exist? So long as our drinking-water has to be filtered, it should not be lawful for a hospital to endanger it through contamination with its foul waste-water.

It seems to me very necessary to lay stress on these points, for I believe that municipal hospitals will in the near future become more and more important to the community. Private hospitals are too expensive to be founded and properly supported except by a few rich men, and our municipal hospitals should not rank in attractiveness and value behind private institutions, but should be at least equal to them. No satisfactory reason can be given why persons of all classes should not be willing to go to municipal hospitals for treatment, and this is not the case to-day. In a well-planned municipal hospital there should be graded accommodations for the rich, the middle class, and the poor. To-day the middle class receive in all our hospitals, both private and public, the worst accommodation. By that I mean that they must usually be treated in the public wards, with the riff-raff of our cities, as they (the middle class) cannot afford to pay for private rooms. A municipal hospital could well afford to have suitable semiprivate rooms, into which the middle class could be received and in which they could be made comfortable without having their proper sense of modesty offended.

It would lead me too far to take up special municipal hospitals, such as those for the insane and those for consumptives, but the general principles I have touched on should apply to them, as well as to the hospitals for other forms of disease. We have happily advanced in our treatment of the insane, but in many parts of our country the conditions still existing in regard to the care of this unfortunate class are a disgrace and scandal, not alone to the immediate community, but also to the public at large, as demonstrating both woeful lack of knowledge on the part of the administrators and sometimes a criminal heartlessness.

It is the duty of us who know what reforms are needed to work harder to secure them, and this brings me to the point of how, after a hospital well suited to the needs of the community is once obtained, it can be properly and successfully administered.

The first essential in order to conduct a municipal hospital well is that all those connected officially with the institution should be men or women trained to fill the positions they hold, and that after they have been appointed their terms of office should be secure, so long as they remain competent and honest. Whether the superintendent should be a man or a woman, lay or professional, seems to me a question of no vital importance. For the larger municipal hospitals I think that, with rare exceptions, the best man that can be obtained is a well-trained physician who has business capacity; but there are laymen who make excellent administrators, and many women (nurses for the most part) who conduct the hospitals of which they are in charge with marked ability. A superintendent of this kind should be paid liberally. His services are worth anywhere from

$5,000 to $10,000 a year. He will, with his business knowledge, save the municipality so much annually as to make his salary seem paltry. The waste and extravagance of our municipal institutions is due largely to the fact that they are managed by both dishonest and incompetent administrators.

Your first question might well be, To whom is the superintendent to be responsible for his acts and expenditures? I reply to a board of trustees, appointed by the mayor or city council, or some municipal board. To indicate more clearly how this can be done, let me take as an example one of the largest municipal hospitals in this country—Bellevue and Allied Hospitals, New York. The mayor makes the appointments from nominations made to him by the Charities Organization Society, the Society of St. Vincent de Paul, and the United Hebrew Charities Organization. Some arrangement of this kind is necessary in a community like New York in order to safeguard the interests of all its citizens, who, as you will note, are represented by a Protestant, a Catholic and a Hebrew society. In most of our communities such an arrangement would not be necessary; but a similar, and, if possible, simpler system is advisable. The trustees should be about eight in number, for, if too numerous, they do not work well together, and, if too few, are often likely not to have the requisite judgment on matters that will come to them for decision. The trustees should, I believe, be laymen, although one physician may be admitted as a member of the board. They should be appointed from the leading citizens, men who have shown their ability in the handling of big business organizations. They should be elected for a period, say, of eight years, two being eliminated every two years and two new members appointed in their places. In this way the good government of the institution can best be assured. The two members whose term expires should not be reelected, except after a lapse of two years. Thus the development of a powerful clique is prevented. The board, having been appointed in this way, should be entirely free from all evil political influence. The trustees should be left entirely free to select the superintendent, who should be a man trained for the position; and once appointed by the board, his term should last indefinitely, under good behavior.

The board should serve in an advisory capacity, and to the superintendent should be left the real administration of the hospital, without any interference on the part of the trustees. He is responsible to them for the efficient and honest expenditure of the sums allowed to him, and his reports should be so minutely detailed that all purchases and expenditures can be readily controlled and approved. The superintendent should be absolutely free in selecting all his assistants, superintendent of nurses, matron, engineer, etc. But it is not worth while to go into the minutiae of these details here. I merely wish to impress on you that the board of trustees is an advisory board, and that the superintendent is, or should be, the true administrative head of the institution. He is responsible to the board, as they are in turn to the community.

Under a commission form of government the administration of the hospitals would be somewhat differently regulated, but it comes down to this in every instance, that the superintendent must be appointed for his ability, not for any political reason, and that he shall hold his office so long as he proves his efficiency. His term shall not depend in any instance on the varying phases of the municipality's political forces. To be an able superintendent, proficient in handling a big business organization, for that is what a municipal hospital is, a man must have special training, acquired only by service as an assistant administrator in various capacities in some large hospital. The position calls for the best men obtainable.

In this relationship it is well to call attention briefly to some of the values and defects of the civil service system. Appointments to many positions in a municipal hospital had best be made under civil service rules, but certain positions should be exempt, and these are the superintendent and any member of the medical staff or of the nursing staff. Clerks, orderlies, helpers, maids, etc., are best protected by being under civil service rules, for in this way they avoid all danger of being unjustly dismissed. The civil service system cannot by any examination select the best man for superintendent or the best nurse as head of the nursing staff. No examination can test honesty and executive ability or the other qualities which combined make a good executive officer. So for this reason, these higher positions should not be classified under the civil service system. No hospital can be administered well if the superintendent is selected by a written examination. To a superintendent, presupposedly honest and capable, elected by a board of trustees, can safely be left the appointment of his assistants to the higher positions. If it is thought well, such appointments can then be confirmed or ratified by the civil service board. This makes it impossible for the staff to suffer from the spoils system of any political party, and the fact that he has appointed his own aids, renders the superintendent able to accomplish far more than with men eligible possibly under civil service rules, but who have had no experience and have simply secured an appointment because they were bright enough to pass a not difficult examination.

To the board of trustees it remains to elect the medical staff. The board being composed of leading citizens will be readily able to secure the necessary information as to the best physicians and surgeons to compose the visiting staff, whose number should be controlled by the size and nature of the hospital. Their term of office should be until they have reached the age of 63 or 65, but they, like the superintendent, should be removable for cause.

The medical staff will form of itself the medical board, to meet with the superintendent at stated intervals, and through him to pass their recommendations to the board of trustees. The duties of the medical board are to look after the patients and their welfare. It has nothing to do with the business administration of the hospital.

The medical staff should receive suitable remuneration for their services from the municipality, which, in this way, can best secure the services of the best men. It should be a privilege and honor to be connected with a muncipal hospital, just as it is to be on the staff of a private hospital, and in a few noteworthy instances it is, for example, in Boston, with the Boston City Hospital. I feel convinced that municipal hospitals are in the near future to hold a more important position in the community life, because, as I have said before, private hospitals will be rarer on account of the immense endowment required to support one properly. Hospitals are as necessary to the community as school-houses, and the community should recognize its own duties in supplying its citizens with proper places in which to be cared for when ill or injured. With state universities and state medical schools there must follow as a natural consequence state hospitals, and the administration of these should be as free from "politics" as is the management of our best state universities.

An administration of the kind that I have hastily sketched will secure for our municipalities institutions as ably administered as are our best private hospitals.

Before closing I wish to draw your attention to one point that I shall not discuss at length, for it is an unpleasant one, but one that ought not to be overlooked in our consideration of the present status of our municipal hospitals. Their culpable inefficiency and their inexcusable deficiency in serving the community is in a large measure due to the medical profession. The best physicians have not, up to the present time, generally shown any interest in these hospitals or attempted to make them better. This is partly due to indifference to the public welfare, and partly to the desire to make money, to state it bluntly. Fortunately our indifference to the public welfare is decreasing, but we waste much time in our societies discussing trivialities as to medical ethics, etc., when we had much better be out "doing," forgetting our own little interests in fighting hand in hand with others to aid those who most need our help. Our doctors have often feared to battle for better conditions lest they might lose their positions on the staffs of municipal hospitals, and have lowered themselves to do what the political "boss" told them to do. This is a disgraceful condition of affairs. It exists throughout the country. If the profession will get together and will speak out forcibly for what they know is right and necessary, they will have the people behind them and be able to secure many needed reforms. There is not the least doubt, and it is a reflection on us as medical men, that many of the movements for social reforms which have been and are being accomplished to-day, have not been inaugurated by physicians, but by laymen and by laywomen. We have followed where we should have led.

As you will see, it has been impossible for me to do more than touch on the various points under consideration, and it has been necessary to leave much unsaid. I can only hope to have brought something new and of interest to your attention. The relation of our municipal hospitals to the community is a most important one—one that deserves deep study by all of us.

The Johns Hopkins Hospital.

# ECHINOCOCCUS CYST OF THE PANCREAS

## REMOVAL AND RECOVERY

CHARLES E. PHILLIPS, A.B., M.D.
Chief of Surgical Clinic, Colon Hospital
COLON, CANAL ZONE

I find a twofold reason for reporting this case: first, on account of the great rarity of the condition, and, secondly, on account of the most unusual history and probable mode of infection.

An idea of the incidence of this disease affecting the pancreas may be gained from a brief review of the literature on the subject. Bergmann[1] dismisses the subject with the statement that "echinococcus cysts of the pancreas have been mentioned, but they occur with great rarity." In Keen[2] is found the following: "Hydatid cysts of the pancreas are extremely rare. Masseron was able to collect the records of only five cases. These were first recognized on the post-mortem table. Graham of Sydney writes: 'The hydatid is sometimes found in the pancreas. I have observed it as a cyst about 3 inches in diameter replacing the head of the organ.' Tricomi states, without giving references, that 'seven cases have been recorded.' "

So it may be stated that heretofore the condition has been observed seven times and that at least five of these were found on the post-mortem table, and there was no reference made concerning the other two cases.

V. S., Colon Hospital, No. 47289, a large muscular Russian, aged 35, on Isthmus seven years, came into my outside clinic, June 1, 1913, and gave a characteristic history of duodenal ulcer. The symptoms dated back for a period of nearly seven years. He was admitted to the ward on the same day and carefully observed and examined on two succeeding days. The examination elicited absolutely nothing other than the symptoms of duodenal ulcer. No tumor mass or abnormality could be palpated except a point of tenderness over the duodenum.

June 4, 1913, I operated on him for ulcer and found a comparatively large and thickened ulcer of the duodenum, the inflammatory reaction of which had extended to the peritoneal coat and caused omental adhesions at its most prominent part.

In making a casual examination of the abdomen preliminary to performing a gastrojejunostomy, I felt a cystic tumor mass, oval in shape, about 2½ inches by 3 inches, just to the left of the median line, and bulging the gastrohepatic omentum just above the lesser curvature of the stomach. Careful palpation through a hole cut in the gastrohepatic omentum revealed the mass to be situated in the upper part of the body of the pancreas and extending from near the head to the tail of the organ.

Carefully walling off the surrounding structures with gauze, I opened the cyst and evacuated its contents little by little into a large gall-stone spoon. The cyst had a very thick wall and contained a thick, creamy material, not at all similar to the clear, gelatinous material usually found in echinococcus cysts. There were no daughter cysts, either exogenous or endogenous. The cyst wall came away without any trouble and was thick, grayish, translucent, gelatinous in appearance and quite characteristic of echinococcus cysts.

Dr. S. T. Darling, chief of the board of health laboratory, and Dr. H. C. Clark, pathologist, both of Ancon, demonstrated many characteristic hooklets in the cyst wall. The cyst was surrounded by a brownish débris of putty-like consistency, which showed microscopically much cellular necrosis and degeneration, and many cholesterin crystals. The appearance suggested pancreatic digestion on the cyst wall.

The cavity was lightly curetted and packed with a narrow strip of iodoform gauze, the end of which was brought out at the upper angle of the incision through a large rubber tube. The rubber tube was stitched both to the edges of the cavity and to the skin, providing a channel through which the gauze could be removed and the cavity repacked until it closed up entirely.

For the benefit of the duodenal ulcer an ordinary no-loop posterior gastrojejunosotomy was performed by suture.

A moderate amount of cellular débris came out with the packing for about ten days. The tube was withdrawn and the patient's recovery was uneventful, except for a slight pancreatic fistula which persisted for five weeks.

During his convalescence, I gained from him the following history. He was born in Odessa, Russia, thirty-five years ago. For two years he was robust and healthy; then he sickened and had a disease known as "dedor" (marasmus?) According to the practice of that country then, it was customary to treat children suffering from this ailment by taking them to the abbatoir, stripping them and burying or covering them all over except the face with the entrails of slaughtered animals, or the stomachs were cut open and the patients covered with fresh tripe. The treatment was repeated daily, and this was the treatment given the patient, repeated daily for many days.

---

[1] Bergmann: System of Surgery.

[2] Keen: Surgery, iii.

During his childhood and manhood he has been singularly free from contact with the lower animals that might bring him infection. At an early age he was apprenticed to a machinist. He left Russia when he was 18, and since that time has never been in any part of the world in which echinococcus disease was endemic. He is a man of more than ordinary intelligence, cleanly and careful in his personal habits and able to give a clear and concise account of his life and mode of living. It is improbable that he contracted the infection through any carelessness or ignorance on his part.

This brings us to the consideration of the probable time and manner of infection in this case. For the past seventeen years —since leaving Russia—he has led a cleanly life in a part of the world where echinococcus disease is very rare if not entirely unknown. Consequently, I believe we may infer that the chance of his infection during the past seventeen years was very slight.

Concerning the first eighteen years of his life, conditions were somewhat different. He lived in a country where echinococcus disease occurs and we must admit the possibility of infection taking place at any time; yet he gives a history of his earlier years that would seem to make the likelihood of infection slight. His home had no domestic pets, he never played with cats, dogs, sheep or other domestic animals that might transmit the infection, while his trade, that of a machinist, had a tendency to keep him away from the most common sources of infection.

So we are brought again to consider the chances of infection at the age of 2 years when he was buried repeatedly in the entrails of slaughtered animals, and probably beyond a doubt some of them were of cattle or sheep suffering from hydatid disease. The exceedingly close contact with infection which would be brought about by this treatment would seem to make infection not only possible, but probable. Infection probably occurred by ingestion of the ovum and direct migration of the ovum through the wall of the stomach into the pancreas, where it began to develop.

By the appearance of the cyst I would say it had probably been dead for a long time, perhaps a number of years. While the duration of this cyst is merely a matter of conjecture, the history and circumstances are such that one may say there could well be no stronger evidence to a duration of thirty-three years.

The cyst was in a position in which palpation was impossible and percussion would reveal nothing. As it did not interfere with the function of at least part of the pancreas, I believe that it gave rise to no symptoms which might even lead us to suspect the trouble and would be found only on the operating-table or at necropsy.

I wish to thank Colonel W. C. Gorgas for permission to publish this paper.

**Hexamethylenamin Used to Preserve Caviar.**—Our vice-consul at Moscow writes that the authorities have been petitioned by the Astrakhan Chamber of Commerce to sanction the use of hexamethylenamin as a preservative of caviar until a more satisfactory preparation is found. Of about 1,400,000 pounds of caviar obtained each year by the Astrakhan fisheries, approximately 75 per cent. is exported, and the only preservative thus far found which will keep the caviar fresh is hexamethylenamin. This substance is added to the caviar in the proportion of 1:1300 and therefore, it is claimed, is not present in amounts sufficient to be injurious to health. Approximately 100 pounds of hexamethylenamin are used for this purpose annually.—(*Consular Reports*, Nov. 6, 1913.)

# A NEW OPERATIVE TREATMENT FOR SPASTIC PARALYSIS

## PRELIMINARY REPORT

WILLIAM SHARPE, M.D.
Adjunct Professor of Surgery, New York Polyclinic Medical School
AND
BENJAMIN P. FARRELL, M.D.
Visiting Surgeon, New York Orthopedic Dispensary and Hospital
NEW YORK

The purpose of this article is to offer a new operative treatment in selected cases of spastic paralysis. We have now a series of only twelve cases to report, but the results have been so gratifying and even startling, that we feel justified in making a report of the work that has been done up to the present time. We do not assert that the improvement in all of our cases will be a permanent one (sufficient time has not yet elapsed since the operations), and yet we do not see why the improvement should not continue to be more and more marked as the children grow older.

Spastic paralysis is a condition which frequently results from a lesion of the brain occurring before birth, during birth or shortly after birth. It is characterized by more or less complete paralysis of the part affected, and is associated with a stiffness or spasticity depending on the extent of the involvement of the pyramidal tract; this hypertonicity produces muscular contractures and deformities, usually flexor in type, with a corresponding overstretching of the opposing muscular groups, usually the extensors. In mild cases, however, the spasticity may be so slight as to cause little or no deformity, but merely an awkwardness of the part affected. Frequently athetoid movements of the arms and legs may be observed, and epileptiform attacks, commonly of the Jacksonian type, may occur.

In a large percentage of cases as the child grows older, not only do the spasticity and its resulting contractures increase, but also the mentality of the child becomes impaired, and this mental impairment continues until the child may be considered a defective, or still further an imbecile, and only too frequently an idiot.

The most common lesion of the brain producing spastic paralysis is that of intracranial hemorrhage of the new-born. It is usually due to a rupture and tear of either the longitudinal sinus or of its venous tributaries, and of vessels overlying the cortex of the brain, causing a hemorrhagic clot to form over the cerebral cortex. According to the extent and pressure of this hemorrhage over the cerebral cortex, we find clinically the signs of such interference of the pyramidal tract—a spastic diplegia, paraplegia, hemiplegia and the milder forms of spastic paralysis. These lesions form 70 per cent. of the cases of spastic paralysis, whereas agenesis and maldevelopment of the cerebral cortex and the cases of meningo-encephalitis complicating measles and scarlet fever constitute most of the remaining 30 per cent.

The operations which have been used in the past and are still being used to improve the conditions of spastic paralysis, namely, tenotomies, tendon lengthenings, sections of the posterior nerve roots, alcohol injections of peripheral nerves, nerve resections and other operations, are, in our opinion, of only temporary benefit, and we have yet to see a case in which the spasticity has not returned, in some degree, within one year. In all of our cases treated by the operations just mentioned during the past two and one-half years, the spasticity began to reappear within one year after operation.

Tenotomies, besides being unsurgical, are unsatisfactory. Tendon lengthenings (Hibbs' operation) alone are satisfactory in only very mild cases. Foerster's operation for sectioning of the posterior nerve roots of the spinal cord is advocated merely to lessen the irritability and the instability of the cortex of the brain by decreasing the number of afferent stimuli reaching the brain through the posterior nerve roots of the spinal cord and also to affect the reflex mechanism of the spinal cord. Besides being a rather formidable and long operation for a child, the lessening of the spasticity is only temporary, few cases being reported improved longer than one year. Our experience with seven cases has been the same. The injection of alcohol into the peripheral nerves (the Allison and Schwab operation) produces immediate paralysis and a temporary relief from spasticity; in our experience of thirty-one cases, however, the spasticity has returned within one year. With nerve resections (Stoffell's operation), we have had no experience. These operations, however, do not in any way "get at" the primary cause of the spastic paralysis, namely, the lesion of the brain, but are merely peripheral operations to relieve the spasticity temporarily, in the hope that, before the recurrence of the spasticity, sufficient power will have returned to the opposing muscular groups to reestablish the muscle balance. Little, if anything, has been done to improve permanently the condition of spastic paralysis, and we offer our observations in the hope that they may lead to a more satisfactory solution of the treatment of these pitiful cases. Our attention was first centered on the importance of relieving the increased intracranial pressure as a means of lessening the spasticity and improving the mentality of these children, by a decompression operation performed by one of us.

### REPORT OF CASES

CASE 1.—The patient, a child, aged 9, with a left spastic hemiplegia of the flexor type, was moribund at the time of operation, having been in status epilepticus for three days, with little or no nourishment. Artificial respiration and oxygen were being used. The intracranial pressure was very high as shown by an ophthalmoscopic examination and by the signs of medullary compression, and therefore a decompression was performed in the hope that a lowering of the intracranial pressure would afford the child its only opportunity to recover. The usual incision was made. The dura was very tense, and when it was incised, cerebrospinal fluid spurted to a height of 4 inches. Signs of an old cortical hemorrhage were found, and 2 cm. above the upper bony margin of the decompression opening was a rather hard, fibrous tumor, the size of an English walnut. As the condition of the child was precarious, it was thought wiser to remove the tumor at a subsequent operation. The child made an excellent recovery; the spasticity, however, lessened to such a degree that he can walk now with only a slight limp, the heel touching the floor; the left arm and the left hand are now being used for the first time in his life. The after-treatment is being carried out now with the cooperation of the child—something impossible before operation. As the child has improved so much, the parents have not yet consented to the second operation for removal of the tumor.

CASE 2.—The patient, a child of 13, with a history typical of intracranial hemorrhage of the new-born, was a spastic hemiplegic, and on ophthalmoscopic examination, signs of intracranial pressure were observed. Remembering the improvement of the preceding case following a mere decompression operation, we advised and obtained consent for the operation merely to relieve the intracranial pressure in the hope that the spasticity would be lessened and the mentality improved. Similar improvement followed as in the preceding case, although a lengthening of the Achilles tendon was deemed advisable and it was performed the following week.

Since then we have performed the decompression operation in twelve selected cases in all and practically the same improvement has resulted in each case. We have selected for operation only the extreme types of spastic cases.

### METHOD OF PROCEDURE

In those cases of spastic paralysis of the hemiplegic, paraplegic or diplegic type, with a definite history of difficult labor with or without the use of instruments, in which, on ophthalmoscopic examination, signs of intracranial pressure are shown in the dilated retinal veins and a blurring and haziness of the optic disks, especially of their nasal halves, a large right subtemporal decompression is performed to relieve the intracranial pressure. If the intracranial pressure is extremely high and remains high after operation, a left subtemporal decompression is performed the following month, the operative recovery requiring only a week to ten days.

The method of dealing with the various pathologic lesions found at operation will be discussed in detail in the more complete report to be published later. The usual findings are definite cystic formations resulting from a cortical hemorrhage occurring at birth. The decompression operation is performed merely to offset the effects of the pressure of this hemorrhage with cystic formation, and the resulting spasticity and mental impairment.

The after-treatment consists in the correction of deformities by tendon lengthenings or stretchings of the contracted muscles, the maintenance of corrected positions through the employment of especially adapted and properly fitting braces, and skilled massage in conjunction with short applications of galvanism and faradism, particular attention being given to the weakened and overstretched muscle groups. A careful, systematic course in muscle training is carried on daily.

The improvement in our cases selected for operation has been so marked—not only a lessening of the spasticity, but a definite amelioration of the mental condition of the patient—that we believe a cranial decompression is indicated in those cases of spastic paralysis showing intracranial pressure by the ophthalmoscopic examination; of those cases of spastic paralysis which we have examined, about 60 per cent. have shown signs of intracranial pressure, and are, therefore, in our opinion, cases that can be very much improved. This operation is not a formidable procedure for one trained in neurologic surgery; all of our patients have improved and we have had no deaths. The anesthetic should be administered by an expert.

One of the most important advantages of this operation is that the child improves mentally to such a degree that we obtain the cooperation of the patient in the carrying out of the after-treatment.

Naturally, we do not believe that all cases of spastic paralysis should have a cranial decompression; in some mild cases, tendon lengthenings alone are sufficient, and this is especially true in the absence of mental impairment. But those selected cases of spastic paralysis, particularly of the hemiplegic and of the paraplegic types, which show signs of increased intracranial pressure by an ophthalmoscopic examination, are the cases that can be very much improved by such a procedure. The cases of agenesis and maldevelopment of the cortex of course cannot and do not show signs of increased intracranial pressure, and are therefore easily excluded by an ophthalmoscopic examination.

A more complete report will be published later.

## IMPROVED TECHNIC FOR BLOOD-COUNTS: RAPID METHOD FOR SECURING EXACT AMOUNT OF SUSPENSION

Allan Eustis, B.S., Ph.B., M.D., New Orleans
Assistant Professor of Dietetics and Nutrition, Medical Department of the Tulane University of Louisiana

Many clinicians regard total white or red counts as an arduous and lengthy procedure. After noticing that most of their time has been consumed in trying to drop the exact amount of suspension on the counting-chamber, I feel justified in calling attention to the technic which I have found for many years both rapid and exact. It may be original or I may have observed some one else doing the same thing, but so far as I know it is original, and none of the text-books on laboratory technic covers the point in question, being content to say: "A small drop of the solution (?) is carefully placed on the center of the counting-chamber, that is, over the ruled scale. The cover-glass is immediately adjusted before the corpuscles can sink, and pressed down at the margin until Newton's rings appear. If these do not remain after removal of the pressure, the preparation *must be made over again.*"

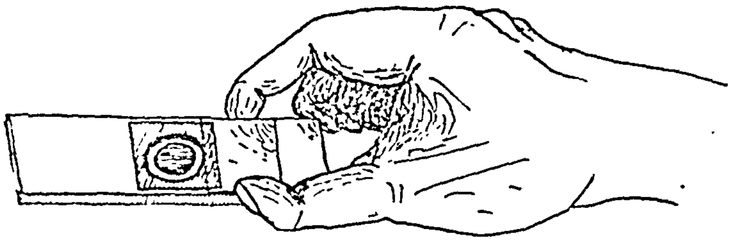

Fig. 1.—Manner of holding cover-glass.

I have observed some clinicians make as many as five or six preparations before obtaining satisfactory results, which can be readily obviated in a single preparation by adhering to the following technic:

After the usual shaking of the pipet, and expulsion of a few drops of the suspension, a good sized drop is placed on the counting-chamber, no particular attention being paid to its size. The cover-glass, which has been previously cleaned, is then rapidly grasped between the thumb and index-finger of the right hand (Fig. 1 and Fig. 2*A*), while the slide is steadied on the table with the left hand. While firm pressure is exerted on the cover-glass it is rapidly slid across the counting-chamber, through the drop of suspension on it. The cover-glass will cut through the drop at exactly 0.1 mm. The excess from the drop will rise on top of the cover-glass and jump across the moat (Fig. 2*B*). Newton's rings will be obtained in each instance. The drop on top of the edge of the cover-glass is wiped or soaked up with the point of a towel or blotting-paper and the preparation is completed.

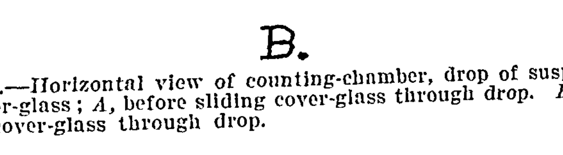

Fig. 2.—Horizontal view of counting-chamber, drop of suspension and cover-glass; *A*, before sliding cover-glass through drop. *B*, after sliding cover-glass through drop.

Precautions to be observed are:

1. Clean cover-glass.
2. Perfectly dry moat.
3. Rapid and perfectly horizontal motion of the cover-glass.

## PUERPERAL INFECTION

(*Concluded from page 1901*)

### TREATMENT OF PUERPERAL INFECTION

If some form of puerperal infection has occurred, of course the first decision is as to whether or not it is local or general. In a local or pelvic disturbance with more or less rise of temperature but without any symptoms of general infection, the treatment should be conservative and more or less symptomatic. The bowels should be carefully attended to, the diet should be simple but sufficient, large amounts of water should be drunk to dilute all the secretions, and Fowler's position should be used more or less continuously to encourage drainage. Again, vaginal douches generally should not be given.

It has been shown that the action of yeast increases leukocytosis and more or less inhibits intestinal intoxication; therefore its administration is good treatment in most infections and is very valuable in pelvic infections. From one-sixth to one-fourth of an ordinary compressed yeast-cake, dissolved in a glass of water, should be given three times a day, unless it causes too much looseness of the bowels. Vaginal douches of yeast solutions have been used and are said to be of value.

Of course the vaginal discharge, or, better, the uterine secretion directly obtained, should be studied bacteriologically to decide, if possible, what infection is present. According to Watkins,[1] the bacteriologic examination of vaginal and uterine secretions is of relatively small value, as the results are often uncertain and misleading. Blood-cultures are the only means at present of accurate diagnosis of the variety of infection. The result of this examination may suggest the use of an antiserum or a vaccine, if either be deemed advisable. The blood should also be examined for pathogenic bacteria.

If a parturient patient has a sudden chill more or less severe, with a rapid rise of temperature which persists in some degree and is not intermittent, and a rapid pulse, puerperal infection has probably developed, unless some serious condition like pneumonia is about to occur. Other symptoms of this general streptococcic infection are: a diminished amount of lochial discharge, perhaps even without odor; more or less tenderness in the pelvic region; a coated and perhaps dry tongue; bad, perhaps septic, breath; scanty urine; severe lumbar pains; tympanites; at times yellowing of the skin, and later, if the infection progresses and becomes serious, possibly delirium. The progress of the fever is that of a typical septicemia. There may be irregular chills, profuse sweatings and more or less leukocytosis. If the lungs, breasts, kidneys and throat have been excluded as the location of the cause of the temperature rise and onset of symptoms, and if the uterus is tender and enlarged, as it generally is, acute puerperal streptococci infection is in evidence.

The insistence here should be on the fact that because there is a septic puerperal infection, it is not forthwith an indication for a uterine curettage, or intrauterine or vaginal douching or any other severe operation. The general treatment just outlined for a more localized simple puerperal pelvic infection should be carried out, with more or less tepid spongings to control the high temperature. The bowels should be freely moved each day, large amounts of water should be drunk and perspiration should be encouraged, though the body should be kept clean by frequent warm spongings and alcohol spongings. The outdoor treatment in Watkins' opinion[1] is the most valuable remedy known as yet in the treatment of puerperal infection. The beneficial effects of that treatment in his cases have been very noticeable, especially as regards improvement in appetite, sleep, temperature and pulse.

---

[1] Watkins, T. J.: Puerperal Infection, Am. Jour. Obst. and Dis. Women and Child., September, 1913; abstr., The Journal A. M. A., Oct. 18, 1913, p. 1485.

The heart may be stimulated by infrequent doses of strychnin, not more than 1/30 grain once in six hours, with caffein (perhaps best as coffee) twice in twenty-four hours, if no delirium is present. Camphor is another valuable cardiac and nervous stimulant and 20 or 30 drops of the official spirit of camphor, given properly diluted once in four to six hours, is good treatment in these cases. In emergencies, one, two or three injections of a sterile ampule of camphor solution in oil hypodermically at intervals of an hour will, at times, tide over cardiac depression. Alcohol may or may not be indicated, depending on whether or not the patient can take other nourishment. It should not be used as a stimulant, and the dose should not be large. Whether ergot or hydrastinin should be given must be decided in each case. The ergot will improve the tone of the circulation, but may cause the uterus to contract more than is desirable. Digitalis should not be used except, perhaps, early in the disease, as the inflamed or injured myocardium which results from an infection must not be hurt by the strong contractions which are caused by this drug.

Fowler's position should be maintained to promote drainage, often with the use of uterine retention tubes, and the Murphy drip may be advisable.

The diagnosis of a streptococcic infection having been made, the choice of one or more of the following specific treatments are available:

1. Antistreptococcic serum.
2. A stock streptococcic vaccine.
3. An autogenous vaccine developed from the uterine secretion.

Antistreptococcic serum has in some hands shown wonderful results; in other hands it has failed. It should be used, if at all, in large doses, as it does not seem to do any harm. It often, however, is not at all antitoxic to the bacterial infection from which the patient is suffering.

If vaccines or bacterins are to be used, they should be used early, and the stock vaccine selected must be polyvalent, that is, it must represent several strains of streptococcus, with the hope that one of them will be the one that has infected the patient. Later, these vaccines are not valuable, as then enough of such stimulation is going on in the patient. Therefore, in the advanced or later stages of the infection an antistreptococcic serum, if it were antitoxic to the germ from which the patient is suffering, would be of great value.

If an autogenous vaccine is to be used, it should be produced early in the infection (such a bacterin, in emergencies, can be developed in from eighteen to twenty-four hours) and immediately given. More than one or two repetitions of such an autogenous vaccine at twenty-four-hour intervals would be doubtful therapy, as in an acute infection such as puerperal septicemia the blood is soon producing all of the antibodies that it can. This is a very different process from a slow-going acute or chronic infection in which revaccinations are often of great value.

As these infections are not malarial, unless a malarial germ is discovered in the blood, there is no excuse for administering quinin. If the diet is without meat, iron should be given, and is, perhaps, best administered in 5-drop doses of the tincture of ferric chlorid in fresh lemonade, given three or four times in twenty-four hours. Also the need of the body for lime should not be forgotten and simple lime-water may be used, or calcium glycerophosphate, in powder, in 0.3 gm. (5 grain) doses, three times daily.

If more or less serious uterine hemorrhage occurs, or if the discharges from the vagina are exceedingly fetid, showing decomposition products in the uterus, it may be necessary to institute some operative interference. Perhaps the safest procedure is to administer an anesthetic and to explore and clean the uterus with the finger properly protected. Curettage of an infected uterus is serious and may cause serious results, to say nothing of the danger of perforating the softened uterine wall. It may be repeated that except for serious hemorrhage it is probably rarely advisable to clean out the uterus during septic infection. Decomposition will generally cause a loosening of foreign and pathologic tissues from the walls of the uterus, and they will generally be passed out through the vagina. Also, it should be remembered that in this septic infection the uterine muscle itself is more or less inflamed and softened, and contains, as well as the surrounding lymphatics, more or less of the infecting germ. Also, when the infection is well in progress the bacteria are probably in the blood. Severe local measures, therefore, do not eradicate the disease and may open up other avenues of absorption. It may even be wise, in the presence of uterine hemorrhage, to pack the vagina first to see if the loosening membrane or piece of placenta will come away without actual uterine interference.

It should be urged that intra-uterine injections and douches are rarely, if ever, indicated, are generally dangerous and may do serious harm. Vaginal douches in septic infection, while not so dangerous, may also cause harm and should generally be omitted. In other words, the pressure in the uterine and vaginal cavity should always be negative to the pressure on the other side of the blood-vessels and lymph-vessels to promote exudation into the parturient canal rather than absorption from this canal. There is danger, also, in intra-uterine injections of forcing septic matter into the fallopian tubes. If, later, a pelvic mass is found, whether hematoma or abscess, hot vaginal douches may be allowable and of value in promoting absorption or in hastening localization for vaginal incision and evacuation.

If there is more or less peritoneal inflammation and, therefore, pain, morphin is indicated, as a patient should not be allowed to suffer pain, for depression from acute pain may be the last straw to stop an already weakened heart. Local applications to the lower part of the abdomen in the shape of turpentine stupes or alcohol fomentations may sometimes be of value as counterirritants. Warm applications, as flaxseed poultices, may give some comfort and prevent the necessity of giving much morphin. They often cause a relaxation of the muscular tissues and lessen the irritation and tension. Of course such treatmeint is purely symptomatic and entirely non-specific. If serious infective localization occurs in the pelvis, more serious operative interference may be necessary.

In recovery from this very dangerous infection the convalescence is long and tedious, and months generally elapse before there is a return to normal health.

## THE REINSPIRATION OF EXPIRED AIR

It is evident to the most superficial observer that under ordinary conditions of breathing some of the expired air must be drawn back again into the lungs. A few experiments to determine the proportion of the breath that is reinspired have been made during the last fifteen years, but no really thorough study of the question was carried out until the recent work of Crowder.[1] This investigator has studied by ingenious methods the effect of such factors as change of position, body motion, different types of breathing and different temperatures, and in addition has determined the conditions that obtain on the sleeping-porch and in the open air. Nasal breathing is the type especially studied; in mouth-breathing there is little or no reinspiration.

The conclusions that may fairly be drawn from Crowder's work are that (1) a person remaining quiet and indoors will immediately rebreathe from 1 to 2 per cent. of his own expired air; (2) when lying in bed the percentage is higher, rising to from 4 to 10 per cent., depending on the position assumed while sleeping. "Nor does sleeping in the open insure pure air for breathing. The same influences here produce the same relative results that they do inside. When one buries his head between pillow and bedclothes for the sake of warmth, reinspiration is inevitable, and it is not necessarily small in amount." In addition, it must be noted that at each inspiration we reinhale not only some of the air just exhaled, but also the air contained in the nose and larger bronchi — the so-called "dead-space" air. This may amount to one-third of the whole volume in quiet inspiration and not less than one-tenth in deep breathing.

The significance of this study in connection with questions of ventilation is obvious. Since even under the most favorable conditions we cannot avoid drawing back into the lungs some of the air that has just passed out of them, not much importance can be attached to the slight variations in carbon dioxid content which occur in the air of rooms. A little deeper breathing seems to be the utmost physiologic effect that could be caused. These experiments also furnish additional evidence against the theory that efficient ventilation consists in the chemical purity of the air, in its freedom from "a toxic organic substance." Even were a poisonous protein substance present in the expired air—a fact no experimenter has yet been able to demonstrate—the human organism under every-day conditions is apparently well able to adjust itself to the reinhalation of this hypothetic substance, since a considerable quantity of the expired air is always taken back into the lungs.

The failure of many expensive ventilation systems to confer the comfort expected from them has been due to neglect of such facts as those here cited. The attempts to "renew" the air by displacing a certain volume at regular intervals were primarily based on the theory that good ventilation was due to freedom from the chemical constituents of expired air. We now know that this practice did not achieve the end aimed at, because the essential factors in good ventilation are not freedom from carbon dioxid or from a mythical organic poison, but are coolness, dryness and motion. Crowder's work brings the old and new theories of ventilation into sharp contrast. "The theory of displacement does not sufficiently take into consideration that all animals possessing lungs ventilate them on a very simple principle of dilution; nor does the pure air theory sufficiently consider that the air of the lungs always remains highly contaminated with their own excretory gases, and that there is such an effective barrier as the dead space against the lowering of the contamination."

## ACIDOSIS AND METABOLISM IN DIABETES

In the course of their elaborate studies on metabolism in diabetes, carried out at Boston in the Nutrition Laboratory belonging to the Carnegie Institution of Washington, Benedict and Joslin[1] have reached the significant conclusion that the exchange of matter and energy is distinctly augmented in the course of this disease. This heightened metabolism is not attributable to psychic influences, excessive muscular exertion or increased protein decomposition. Contributory causes like fever and the factors just mentioned were carefully excluded. The tendency toward increase in metabolic exchange appears to parallel the alteration in the intensity of the diabetes.

Acidosis and the attendant production of the compounds leading to ketonuria are a characteristic of the severer types of diabetes. It seems not unreasonable therefore to connect the acidosis with the simultaneously augmented metabolism. Ketonuria can readily be induced in perfectly healthy subjects by the complete withdrawal of carbohydrate from the diet and likewise by starvation. It is only logical, therefore, to ascertain the effect on the metabolism in normal man of an acidosis thus artificially induced. New experiments conducted likewise in the Nutrition Laboratory at Boston[2] have given clear-cut evidence of the stimulation induced in this way.

---

[1] Benedict, F. G., and Joslin, E. P.: Metabolism in Diabetes, Publications of the Carnegie Inst. of Washington, No. 135; A Study of Metabolism in Severe Diabetes, ibid., No. 176.

In the experiments here referred to the quantities of beta-hydroxybutyric acid found in the excreta during the period of increased metabolism did not exceed 5 gm. per day. This is far outdone by diabetics, who may show an output of more than 50 gm. with no greater rise in the metabolism than the normal subjects showed in the presence of the smaller amount of acidosis products. It is therefore conceivable, as Benedict and Joslin point out, that the continued production and presence of beta-hydroxybutyric acid as it must occur in the organism of the diabetic develops a degree of tolerance to its specific metabolism-stimulating effect. Whether the latter is in reality a direct action of the circulating acid on the tissue-cells or is due to the diminished alkalinity of the blood remains to be learned. In fact, for the present one is not justified in going beyond the demonstration of the usual simultaneous manifestation of acidosis and heightened metabolism, for in cases of prolonged starvation it has been missed.

In accord with clinical experience the Boston investigators offer the significant reminder that an acidosis of moderate intensity induced by the sudden withdrawal of carbohydrates is more dangerous than a decidedly more severe acidosis attending the more gradual initiation of a carbohydrate-free regimen. The sudden withholding of carbohydrates, which is liable to occur when a diabetic patient enters a hospital or has a change of physicians, may precipitate an acute onset of coma. It is surprising, we are told, how small may be the urinary output of organic acids in such cases. On the other hand, patients with severe diabetes who have been subjected to a strict non-carbohydrate diet for long periods may manifest an acidosis involving 50 gm. of beta-oxybutyric acid in the daily urine without any disturbances directly associated therewith. The sudden complete withdrawal of carbohydrates is always a questionable procedure in diet regulation.

## THE PULSE-RATE DURING SLEEP

The extensive records obtained in the course of the past few years at the Boston Nutrition Laboratory of the Carnegie Institution of Washington have made it evident that there is a close and almost direct relationship in both man and animals between the pulse-rate and total metabolism. If this is true it becomes apparent that under normal circumstances the pulse-rate may be a sort of index of the extent of the chemical changes taking place in the body. Every one realizes from personal experience that muscular movements, which, of course, occasion an increase in metabolism to liberate the energy essential for their performance, are attended with a more rapid heart-beat, the rate varying with the intensity of the exercise performed. The published observations available show, however, that this response of the pulse is more perfect than might be suspected. Not only the more vigorous activities but even unsuspected ones exert detectable influence on the pulse-rate. We recall, for example, the records of Benedict and Talbot[1] on nursing infants. The relationship between carbon dioxid production, pulse-rate and the muscular movements of infants as recorded by graphic methods was very striking. In comparing the pulse of infants of different ages, for instance, a very young baby and an older one, it was noted that there is much less stability of the young babies' pulses than those of the older ones, and a slight motion causes more marked elevation of the pulse. The minimum average pulse-rate depends on the age and type of the baby, and no general rules can be made, because each baby is a law unto itself. The average of the babies in the first week of life was 120 beats per minute and that of the older babies somewhat slower. The average minimum of one baby 3 months old was about 90 beats per minute, and that of another baby of 3 months 100 per minute. Slight movements which were visible practically always elevated the pulse-rate from ten to twenty beats, while violent exercise, such as nursing or crying, increased the pulse-rate from fifty to sixty beats. When the pulse was increased for twenty minutes, as it was during a nursing, it took about ten minutes after the exercise was finished for the pulse-rate to reach the normal. Sometimes it dropped below normal after continued exercise, and remained there for from three to five minutes. The pulse, therefore, did not reach the normal line in some instances until fifteen minutes after the muscular exercise was finished.

The interpretation of the pulse-rate in relation to metabolism at once suggests the bearing of this factor in the daily routine of adult man. No clinical observations are more frequently repeated than those on the pulse-rate, a symptom which every physician continually makes use of at all times of the day. There are, nevertheless, few statistics available respecting the pulse in sleep, a period when muscular activity and metabolism are at a low ebb. Data on this subject have been obtained by Dr. Klewitz in Moritz' clinic at Cologne.[2] The average pulse-rate of persons free from heart defects was fifty-nine per minute during sleep and seventy-four when awake, the subjects in either case being at rest in bed. The variations in the pulse-rate are far less marked than during waking rest. That the lowering of the pulse-rate during sleep is in truth merely the expression of a more decided condition of perfect restfulness is evidenced by the fact that even during waking hours figures as low as those noted in sleep could be observed, provided the degree of rest was as perfect as can be maintained by a person awake. During sleep in the daytime the pulse-rate is scarcely decreased below that which obtains at rest in waking hours.

---

[1] Benedict, F. G., and Talbot, F. B.: Some Fundamental Principles in Studying Infant Metabolism, Am. Jour. Dis. Child., September, 1912, p. 129.

[2] Klewitz, F.: Der Puls im Schlaf, Deutsch. Arch. f. klin. Med., 1913, cxii, 38.

From a clinical point of view it is interesting to note that the conditions just recited also exist in patients with valvular defects in whom the cardiac deficiency has become compensated; but when the latter is not the case the pulse-rate is not so characteristically decreased in sleep. The extent of the decrease in the heart-rate is in a way indicative of the degree of compensatory changes which has been established, so that the comparison of the pulse-rate in sleep and in waking hours may have some prognostic value. Irregularities of the heart, such as extrasystoles, etc., do not disappear in sleep. Tachycardia due to organic defects is likewise not obliterated by sleep; but when the accelerated heart-rate is associated with purely nervous causes, the tachycardia disappears in sleep. Here again the determination of the pulse-rate may furnish a help in differential diagnosis.

## THE CONSEQUENCES OF INTESTINAL OBSTRUCTION

The occasion of the severe symptoms and frequently fatal outcome of high intestinal obstruction and the cause of death from volvulus have of late attracted unusual attention from surgeons and other investigators. Certain facts seem clearly established. High loop obstruction in animals, for example, may cause very rapid death, in from twenty-four to sixty hours, as a rule, even when the loop contains no food material or secretion from the stomach, liver or pancreas. Low loops of similar nature in the region of the ileum appear to be less rapidly productive of fatal results. To quote a few illustrative instances, Bunting and Jones have found that in rabbits obstruction of the duodenum is more quickly fatal than obstruction of the pylorus or of the ileum. Whipple, Stone and Bernheim, among others, have noted that dogs having closed duodenal loops die with symptoms like those of patients suffering from volvulus or high intestinal obstruction. It would take us too far to attempt to review here the important contributions which have been made to the solution of the problems concerned with intestinal obstruction.[1] Some of the debated points seem now to be definitely settled. Thus, among the classic explanations of death in obstruction, infection was early given a prominent place. Hartwell and Hoguet[2] have demonstrated by bacteriologic examination on dogs with high intestinal obstruction that death may result without demonstrable invasion of the blood-stream, peritoneum, liver or spleen by organisms. This and other work practically rules out the infection theory. Murphy (F. T.) and Vincent have championed the view that interference with the circulation of the obstructed intestine is the vital factor in the symptoms of ileus; but we believe that there is abundant evidence that death may occur when the intestinal obstruction is uncomplicated by any circulatory interference. Obviously damage to the intestine produced by disturbances of the circulation, particularly venous obstruction, leads to more fulminant and disastrous reactions than simple obstruction alone; but the circulatory factor is incidental and contributory here, and not the determining issue.

A further explanation of the cause of death in obstruction postulates an intoxication from within the lumen of the bowel itself. The hypothetic toxic substance has been referred by some to the activity of bacteria and to noxious substances arising within the intestinal lumen, whereas others postulate the secretion of a poisonous product by the glandular structures and walls of the alimentary tract. It is about this toxin theory that a vigorous scientific debate has lately been carried on by American investigators. That the poison is derived from bacterial life in the obstructed loops is no longer prominently defended. The bacterial flora of the upper alimentary tract is relatively scanty about the duodenum and upper jejunum and becomes much more luxuriant toward the large intestine. The more recent researches agree in showing that the part of the intestine poorest in bacterial inhabitants is that which yields most rapidly fatal results when obstructed.

There remain for consideration the variously conceived hypotheses involving the production or secretion of a poisonous substance by the mucosa itself. Draper believed that the "toxin" is contained in the duodenal secretion and is normally neutralized by the secretion of the mucosa of the jejunum and ileum. Consequently in obstruction of the upper bowel the harmful outcome was due, on this theory, to the inability of the antidotal product of the lower portions of the intestine to offset the duodenal poison. This purely hypothetic explanation has been made improbable by experiments of Whipple, Stone and Bernheim in which duodenal loop fluid was found to lose none of its toxic character when mixed with normal intestinal mucosa. Bunting and Jones have reached the conclusion that, in rabbits at least, the duodenal mucosa alone secretes the poison, and that it comes from the glands of Brunner and is responsible for the death of animals with obstruction.

The most ardent advocates of the toxin theory are Whipple, Stone and Bernheim. From the results of very elaborate studies they have come to the conclusion that the mucosa of closed duodenal loops, the latter employed because they induce the typical symptoms of death from high obstruction, must form a poisonous substance which is absorbed from it and accounts for the fatal issue. The material from such loops can be prevented from containing bile, pancreatic juice, gastric juice or digestion products, any of which might independently have been responsible for the intoxication if perchance owing to obstruction they were absorbed as such. The toxic substance is not absorbed from the normal intestinal tract. Destruction of the mucosa prevents the formation of the toxic substance, thus furnishing the final proof that the mucosa is the essential factor in the elaboration of the alleged poisonous material.

[2] Hartwell, J. A., and Hoguet, J. P.: Am. Jour. Med. Sc., 1912,
cxliii, 357.

These far-reaching conclusions, charging hitherto unsuspected potencies for harm to the intestinal lining, have been vigorously opposed by Hartwell and Hoguet, who have pointed out that animals with obstruction of the lower duodenum vomit profusely. The urine shows marked abnormalities when compared with the kidney secretion in simple starvation; but if a quantity of normal saline slightly in excess of the total loss of water in the urine and vomitus be given daily in the form of hypodermoclysis, the animals return to the conditions characteristic of simple starvation and may live in excellent health for long periods. According to these investigators, therefore, the important element in the development of the toxic symptoms seen in intestinal obstruction is the hitherto unappreciated loss of water. The symptoms of intoxication are those resulting from tissue disintegration following this loss. When strangulation complicates obstruction, however, these facts do not suffice to explain the outcome.

In his most recent contribution to the subject, Hartwell[3] insists that simple stagnation does not yield a poisonous substance. According to him the only poison present in intestinal obstruction arises from the damage secondary to the obstruction, and not from the stagnation of intestinal contents or an altered function of a normal-appearing mucosa. In explanation of the experience of the opposing school Hartwell points out that in their experiments injury to the intestinal wall has been common, as judged from the necropsy records, and that in the absence of such damage there is no primary toxemia.

Clinical intestinal obstruction is almost invariably associated with a damaged intestine, and consequently it is fair to assume that a poison is produced with this condition. The valuable experimental work in which so many enthusiastic investigators have been active has made it clear that large amounts of saline subcutaneously may be used with advantage, patients having readily absorbed from three to six quarts in twenty-four hours. Hartwell maintains that in man there is no necessity of draining out the intestinal contents, which has been urged by the believers in the theory of a secreted toxin, unless the bowel is damaged. Simple stagnation does not yield a poisonous substance, and consequently the release of the obstruction by operation is sufficient. When, however, strangulation has begun, the material above the obstruction should be removed, and if extensive damage exists, a continued drainage through an enterostomy may be needed.

## THE HEALTH TRAIN AS A STIMULUS TO SANITATION

The value of the health train, now being employed in some states to educate the people on the value of better hygiene and sanitation, is undoubted. It gives direct instruction in personal and community hygienic principles, and the printed reports of the inspectors accompanying the train concerning the towns and villages through which the train passes have become a strong stimulus to sanitary improvement. This is accomplished both through appeals to local pride and through light thrown on specific defects. The State Board of Health[1] of Michigan during the summer ran a health train through the state, touching at many points. Great interest was manifested in the lectures and the exhibits connected with the train. In the report of the inspectors, the sanitary shortcomings of many villages are set forth in plain terms. For instance, of one town it is said: "Health sentiment is at a low ebb here. The health officer was attending a picnic, but the flies were attending to business in the unscreened, filthy privies and garbage-heaps around the town." This particular town is not likely to be proud of this report, and the health officer will undoubtedly begin to clean things up. In contrast to this it was said about another town: "This is the most all-round sanitary little village visited by the special. A good progressive president and health officer, backed by a splendid sanitary sentiment." In many places it was found that the health department was active and efficient, but was not supported by the proper public sentiment. This is the chief shortcoming of most places, on the part both of the citizens and of the city or town authorities who fail to vote sufficient money to carry out sanitary measures effectively. While there was no intention of being hypercritical, the truth was plainly told in the report and without doubt the awakening secured by the health train and the report on sanitary conditions will work a great improvement. Michigan, of course, is not different in this regard from other states, and the report on conditions there would probably apply almost exactly to any state making a similar inspection. The method of teaching personal and public hygiene by the health train is a modern invention that should be encouraged.

## HEALTH PROBLEMS IN JERUSALEM

The triumphs of modern sanitation have furnished so many conspicuous illustrations of what can be accomplished by the practice of the teachings of modern scientific hygiene that the possibilities involved have already become familiar to the reading and thinking public of the United States. The experience of our government alone, culminating in the splendid success of Colonel Gorgas in the Panama Canal Zone, cannot fail to awaken an eagerness to apply comparable measures speedily in all parts of the world where health conditions and sanitary environment suggest the possibility of work in the direction of eliminating disease. A conspicuous instance of the need for such work is furnished at present by Jerusalem, a city in which one out of every five of its 70,000 inhabitants carries the parasite of malaria in his blood and three-fifths of the population give evidence of enlargement of the spleen. These facts, so striking because of the enormous incidence of preventable disease and so pathetic because they mean so large a loss of human usefulness, are not hearsay figures. They are, on the contrary, the outcome of investigations by a scientific commission at the Health Bureau of the Jewish Agricultural Experiment Station in Jerusalem. This laboratory of hygiene, endowed in 1912 by the New York philanthropist Nathan Straus to combat the endemic diseases of Jerusalem, malaria in particular, has rendered a report[1] from which the statements made above have been quoted. The city is not unfavorably situated from the point of view of climate or elevation; nevertheless it is the home of disease in its most varied manifestations. This is due primarily to the great poverty of the population; and added to this is the indifference or ignorance of the Turkish officials in matters of hygiene. In the light of present-day knowledge the pictures of the primitive sanitary arrangements that still obtain in ancient Jerusalem would furnish an interesting object-lesson. As might be expected, *Anopheles* reigns supreme. The chief breeding-places of the mosquito are the cisterns which provide to the inhabitants the water-supply conserved from the rain which reaches the house-tops. Primitive privies are all too frequently found in close proximity to the drinking-water cisterns. It is an old story, the foremost interest in which now lies in the extent of the invasion of disease, especially malaria, and the consideration of the best means for combating this under the rather unusual conditions that prevail in a city where every nationality and religious sect seeks to maintain its territorial and governmental independence under the manifestly helpless jurisdiction of Turkish officials. Elsewhere the extermination of the anopheles mosquito by drainage, the use of petroleum oils, etc., has been effectively combined with prophylactic administration of quinin. A complete and expensive program cannot yet be carried out in Jerusalem. A beginning has been made by the introduction of screening-devices for the cisterns. Bacterial infections are to be eliminated in part by attention to the problems of sewage disposal. It is easy to outline ideal plans for the improvement of the unfortunate conditions which have so long been tolerated in such places as Jerusalem. The actual work of sanitary conquest must, however, keep pace with the advance of general enlightenment and political and economic progress, unless a superior power somehow is introduced which will put an end to apathy in regard to matters of hygiene.

## PUBLIC OPPOSITION TO PROTECTIVE MEDICAL MEASURES

Opposition to legislation designed to regulate the practice of medicine, but almost wholly in the interests of the public, seems not to be confined to this side of the world. A bill introduced into the legislative council of South Australia to make better provision for the registration of medical practitioners, according to the *Australasian Medical Gazette*,[1] has created a great deal of unfavorable comment. Under this bill it is proposed to restrict the practice of medicine and surgery to those legally qualified and registered within the meaning of the act, and all practice by herbalists, dispensing chemists and quacks of all description is prohibited under penalty. The usual objection has been raised that the wording of this particular act might penalize any one who might advise a friend to take a dose of castor oil for a common ailment, or a mother who might help to relieve from pain a neighbor's child. The *Gazette*, in commenting on this opposition, says that it seems almost impossible to drive into the mind of the layman that any "common ailment" may be a symptom of a serious disease, and that the administration of a dose of castor oil to a patient suffering from constipation might be a very serious matter if the constipation were due to strangulated hernia or intestinal obstruction. It is further said that until the general public can be better educated in medical matters some will always be found who prefer to trust their lives to the heaven-inspired herbalist or quack rather than to the educated medical practitioner. It would seem also that the wolf cry, "medical trust," is raised in the antipodes as well as on this side of the earth, for the comment is made that, "unfortunately, the medical profession generally incurs public odium in any attempt to secure legislation which may protect the profession, but which helps to a much greater extent to protect the public. We are accused of attempting to establish a close monopoly. . . . The profession of medicine has a right to be protected from the competition of uneducated and unscrupulous quacks who trade on the credulity of the public, but the general public have still greater need to be protected from themselves and their own ignorance and from the 'assistance' of the writers in the lay press who fail to grasp the seriousness of the situation in advocating the recognition of the herbalist, the optician, the dispensing chemist, as competent to give medical and surgical advice." What a complete and perfect echo is this of conditions on our own side of the world!

## COLLEGE ENTRANCE EXAMINATIONS, JUNE, 1913

During the week beginning June 16, 1913, under the auspices of the College Entrance Examination Board, 4,159 high-school students were examined for entrance to various colleges. The examination covered sixteen subjects, for each of which three examiners had been selected, two being teachers in colleges and one a teacher in a secondary school. Altogether, therefore, there were forty-eight examiners, experts in their various subjects,

1. Australasian Med. Gaz., Sept. 13, 1913.

who prepared the questions for the examination. The examinations were held simultaneously in forty states of this country, and in eight dependencies and foreign countries — altogether, in 170 different cities. The examination in each city was given at some trustworthy educational institution, under selected supervisors and proctors. After the examination papers were completed they were placed in charge of readers who did the grading. This year 147 readers were appointed to grade the papers, and of these, eighty-five were representatives of colleges and sixty-two were representatives of secondary schools. In fees from candidates examined $22,335 was received. For the preparation of the questions and other service the forty-eight examiners were paid $1,629 for salaries and expenses; for grading the papers, the 147 readers were paid $12,562 for salaries and expenses; for supervision of the examinations and for proctors $2,836 was expended for salaries and expenses. Those interested in preliminary examinations should read the Thirteenth Annual Report, which may be obtained from the secretary of the board, Substation 84, New York City. When it is seen that our colleges are arranging a single, well-conducted, thorough and uniform examination covering the secondary school branches, one can but wish that all high-school examinations for admission to medical colleges might also be conducted under the auspices of the College Entrance Examination Board. This would do away with the present confusion of standards and ratings resulting from the multiplicity of agencies now issuing certificates for entrance to medical schools. Here, indeed, seems to be a solution of the gravest problem of our medical schools—the securing of a thorough and reliable "equivalent" credential by those who have not been fortunate enough to complete a course in a standard four-year high school. Here again is an examination conducted along such lines as to place it entirely above suspicion, making it worthy, therefore, of general acceptance.

## DANCING

It seems somewhat late to enter a mild protest against the fervor with which the newest "so-called" dances have been taken up by a public already saturated with various nerve- and mind-destroying amusements and caprices. It seems unnecessary to call attention to the fact that the tango, the various waltzes, the maxixe, etc., are being arduously cultivated by callow youth and calloused old age. The problems created by these dances differ according to the age of the participants; for the young the question of morality is paramount; for the old the possibility of too great a strain on a dilated heart or an arteriosclerotic vessel is apparent. The physician will do well to caution the stiff-jointed, aged patient, who derives too great a pleasure from these — to him — potentially harmful amusements.

**All Treatment an Experiment.**—All treatment, however carefully chosen, is in the nature of an experiment, for none can know the exact effect of any treatment or drug on any individual patient until he has tried it. A drug may suit ninety-nine persons but be injurious to the one-hundredth because of some idiosyncrasy.—F. M. Sandwith, in *Clin. Jour.*

# Medical · News

## CALIFORNIA

**Typhoid Inoculation at University.**—Antityphoid inoculation is being administered free to the students and faculty of the University of California. Thus far immunization is optional.

**Hospital Dedicated.**—The new Mercy Hospital, Bakersfield, was dedicated November 9, with impressive ceremonies by Right Rev. Thomas Conaty, bishop of Monterey and Los Angeles.

**Sanatorium Incorporated.**—The Oaks Sanatorium has been incorporated at San Jose with a capital of $50,000, and the following officers have been elected: president, Dr. Richard F. Tomlinson, San Francisco; secretary, Dr. Lily Boldemann, San Francisco; treasurer, Dr. William Boericke, San Francisco, and medical superintendent, Dr. Mary C. MacInnes, Los Gatos.

**Fund for Medical Building.**—The Board of Regents of the University of California announced November 11, the completion of the additional fund of $600,000 for the erection of the hospital building which is to be a part of the College of Medicine of the University. It was stated that the principal donations to the fund were from Mr. and Mrs. William H. Crocker, Templeton Crocker and Mrs. C. B. Alexander, New York, who contributed $150,000, and John Keith who also donated $150,000. A committee was appointed to administer the fund and supervise the erection of the building.

**Personal.**—Dr. J. M. G. Carter, Los Angeles, has donated his medical library and many scientific books to the University of Southern California.——Dr. C. L. McKown, Niles, who has been ill with septicemia at Pacific Grove has recovered and resumed practice.——Dr. Charles T. Palmer, assistant health officer of Los Angeles, is said to have been committed to the State Hospital for the Insane, Patton.——Fresno County Medical Society was entertained at dinner by Dr. C. T. Rosson at his home in Hanford, November 4.——Dr. C. H. Adair, Fresno, was struck by a street-car November 4 and seriously injured.——Dr. A. F. Gillihan, Berkeley, has been appointed health commissioner of Oakland as the result of a competitive examination.

## ILLINOIS

**Death of Dr. W. K. Newcomb.**—As we go to press we learn *of the death of Dr. W. K. Newcomb of Champaign.*

**Contract Let for Hospital.**—The Cook County Board has awarded the contract for the tuberculosis hospital and other buildings at Oak Forest for $581,467.

**New Officers.**—Fox River Valley Medical Society at Aurora, November 18: president, Dr. Raymond G. Scott, Geneva; vice-president, Dr. Ora L. Pelton, Elgin.

**Health Bureau for LaSalle.**—Through the beneficence of Mr. F. W. Matthiessen, LaSalle, the cities of LaSalle, Peru and Oglesby are to have a model health bureau in charge of an expert commissioner, health officers and sanitary inspectors. The expense of the undertaking will be about $20,000.

**Personal.**—Dr. and Mrs. John A. Pratt, Aurora, and Dr. Carroll B. Welton, Peoria, have returned from abroad.——Dr. Rockwood Sager is reported to be critically ill with a cerebral hemorrhage at his home in Rockford.——Dr. and Mrs. Theophil J. Holke, Peotone, sailed for Europe November 22.——Dr. Harry M. Hayes, Peoria, is seriously ill with typhoid fever in Proctor Hospital.

### Chicago

**Physicians' Club.**—At the opening meeting of the Physicians' Club of Chicago December 5, at the Hotel Sherman, Prof. George A. Dorsey of the University of Chicago will preside and Lieut.-Col. Charles E. Woodruff, M.C., U.S.A. (retired), will speak on "Medical Ethnology."

**Personal.**—Dr. and Mrs. Plumer M. Woodworth, who have been spending four months in California, have left for Honolulu, where they will spend the winter.——Dr. Sarah A. Noble has returned from Europe.——Dr. Andrew M. Harvey has been elected president of Local Council No. 3 of the National Council for Industrial Safety.——Dr. and Mrs. Charles Adams left Chicago for their new home in Honolulu, T. H., November 22.

## MASSACHUSETTS

**Sanatorium Fire.**—Fire in one of the buildings of the Ring Sanatorium, Arlington Heights, November 17, necessitated the transfer of five patients and caused damage amounting to $2,000.

**New Officers.**—Boston Society of Medical Science at Harvard Medical School, November 18: president, Dr. Theobald Smith; vice-presidents, Drs. Henry A. Christian and David L. Edsall; secretary-treasurer, Dr. Thomas Ordway.

**New Antituberculosis Officers.**—At the annual meeting of the Springfield Association for the Prevention of Tuberculosis, November 12, Dr. George L. Schadt was elected president, and Drs. Allen G. Rice, Edgar H. Guild and Ralph B. Ober were elected members of the executive committee.

**Hospital Staff Election.**—At the annual meeting of the North Adams Hospital Staff November 10, it was announced that Mrs. A. L. Hopkins, Williamstown, who gave the laboratory to the hospital a year ago, is offering to provide an assistant to the pathologist of the institution. Dr. Augustus K. Boom, Adams, was reelected president and Dr. Francis J. O'Hara, North Adams, vice-president, and a conference board consisting of Drs. Martin M. Brown, Frank D. Stafford and John R. Hobbie was named to confer with the hospital authorities on matters pertaining to medical attendance at the institution.

**Reporting of Occupational Diseases.**—The State Board of Labor and Industries and the Industrial Accident Board are making arrangements through subcommittees for a public hearing at the State House in regard to the adoption of a regulation requiring all physicians to report occupational diseases to the joint board, this hearing to be held as provided for by Section 2, Chapter 813, Acts of 1913. Representatives of all the medical societies of the state and physicians generally will be invited to attend the conference, and the meeting will be addressed by the experts engaged by the special committee created by the joint board, James B. Carroll, James A. Lowell and Mrs. Davis R. Dewey. Arrangements for the proposed meeting are in the hands of a subcommittee, consisting of James W. Crook, Joseph A. Parks and Channing Smith. It is expected that a comprehensive plan for the reporting of occupational diseases will be developed as a result of the conference.

**Mental Diseases and Alcohol.**—A conference on the problems of mental disease due to alcohol, open to physicians and officials dealing with the alcohol problem, was held in the assembly room of the Psychopathic Hospital, Boston, November 24, under the auspices of the trustees of the Boston State Hospital and the legislative committee on drunkenness. After introductory remarks by Dr. Walter Channing of the Boston State Hospital, the scope of the work of the Massachusetts commission on drunkenness, 1913, was detailed by Hon. M. J. Murray, chairman of the commission; Dr. H. M. Adler described, with clinical demonstrations, types of alcoholic mental disease at the Psychopathic Hospital; Dr. T. E. Eversole read a paper on "Consensual Amyosis to Blue Light as Shown in Alcoholic Cases." Dr. H. M. Adler made some further remarks on therapy, especially hydrotherapy in various hyperkinetic states; Drs. A. W. Stearns and Mary C. Jarrett presented notes on the after-care and moral suasion work with alcoholics in the outpatient department of the Psychopathic Hospital, and Dr. E. E. Southard, director of the hospital, discussed "The Alcohol Problem Viewed From the Angle of the Psychopathic Hospital." The presentation of these papers was followed by a general discussion.

## NEW JERSEY

**New Jersey Sanitary Association.**—The thirty-eighth annual meeting of the New Jersey Sanitary Association will be held at the Laurel-in-the-Pines, Lakewood, December 5 and 6, under the presidency of Dr. Benjamin VanD. Hedges, Plainfield.

**New Officers.**—Mercer County Medical Society at Trenton, November 11: president, Dr. Harry R. North; secretary, Dr. Walter A. Taylor, both of Trenton.——Tri-County (Salem, Gloucester and Cumberland) Medical Society at Bridgeton, October 28: president, Dr. E. S. Corson, Bridgeton; secretary-treasurer, Dr. George E. Reading, Woodbury.

**New Board of Health Building Dedicated.**—The new four-story Board of Health building at William and Plane Streets, Newark, was dedicated with simple ceremonies, November 8. The keys of the building were turned by the mayor to Dr. Herman C. H. Herold, the health officer, but the Board of Health will not occupy the building until the first of the year.

**Pavilion Plans Approved.**—The preliminary plans for the proposed tuberculosis pavilion and hospital annex at the Overbrook Hospital for the Insane were approved by the freeholders' committee at Newark, November 10. The pavilion will accommodate sixty-seven women and fifty-five men and will cost about $130,000. The proposed additional hospital wing, which will accommodate 200 patients, will be 200 by 40 feet, and will cost about $180,000.

## NEW YORK

**Health Department Exhibit at State Fair.**—The State Department of Health installed an entirely new health exhibit at the state fair this year. It was divided into three sections: Home and farm sanitation, care of the baby and the child's health at school. In the sanitation exhibit there was a landscape model illustrating the pollution of streams through a large stretch of country; a model of an inexpensive sewage disposal plant for a country house, and models showing the pollution of well water and the layout of a sanitary farm.

**Epidemic Sore Throat.**—Numerous cases of septic sore throat and glandular involvement have been reported from various portions of the state. The patients have frequently been ill for several days with mild sore throat and temperatures of from 101 to 102 F. for several days. There is sometimes a light induration of the lymphatics at the angle of the jaw. The condition seems to be very communicable and the State Health Department recommends that patients suffering from this condition should be isolated and not allowed to mingle with other members of the household. It is also recommended that cultures be taken from the throats of all who come in contact with such cases and that they be watched to see if sore throat, or glandular enlargement, or possibly a rash or desquamation follows in two or three weeks.

### New York City

**Harvey Society Lecture.**—The fourth in the present course of Harvey Society lectures to be delivered at the New York Academy of Medicine November 29, at 8:30 p. m. by G. H. Parker, Harvard University, is on "The Nervous System; Its Origin and Evolution."

**Street Fatalities for October.**—During October thirty-six children were killed in New York City by automobiles and other vehicles. This number is the highest on record and brings the total of children killed by all classes of traffic since January up to 227. Automobiles have furnished 60 per cent. of the victims of traffic in Greater New York. The National Highways Protective Association urges better playground facilities or any policy which will relieve congestion of population as a material aid in decreasing the number of street deaths by accident.

**Corner-Stone of New Dispensary Laid.**—The corner-stone of the new dispensary in connection with the Hospital for Deformities and Joint Diseases was laid on November 4. Among those who made addresses were Dr. Abraham Jacobi, Rabbi Maurice Harris, Judge Julius Mayer, Dr. Reginald Sayre and Felix Warburg. Dr. Herman C. Frauenthal is surgeon in chief of the hospital, which during the past year has taken in 4,023 new cases, 600 more than in 1912, and 3,811 more than in 1907. It was announced that $50,000 more was needed to complete and equip the dispensary.

**Personal.**—Dr. James W. Jobling of the Morris Institute for Medical Research in Chicago has been appointed assistant professor of pathology to succeed the late Dr. Hugh Angus Stewart.——Dr. Frederick S. Lee, Dalton professor of physiology of Columbia University, has been appointed delegate to the University Council from the faculty of medicine, to serve until June 30, 1916.——A memorial window to the late Dr. James Edward Newcomb has been placed in the hall of the Stony Wold Sanatorium, Lake Kushaqua, N. Y., and dedicatory exercises will be held there October 22.

**Society for Advancement of Clinical Study Begins Work.**—The Society for the Advancement of Clinical Study in New York issued its first bulletin of clinics for November 7. The society maintains a bureau at the New York Academy of Medicine, where the list of operations open to physicians is posted daily, together with the time of operation and the name of the operator. The bulletin of operations will be mailed to any physician for 50 cents a week, and to hospitals sending in regular reports of their lists of operations, it will be sent free of charge. It is believed that this method of informing physicians of the city what is being done in the various clinics and making it possible for them to visit these clinics is a great step in advance in dissemination of medical knowledge.

## OREGON

**Alumni Banquet.**—The Alumni Association of the Medical Department of the University of Oregon held a meeting and banquet in Portland October 13. Dr. William E. Smith, president of the medical branch of the Alumni Association, acted as chairman, and Dr. A. G. Bettman as secretary.

**Meeting of Eastern Oregon Physicians.**—The annual meeting of the Eastern Oregon Medical Society was held at Hot Lake October 29. Dr. M. K. Hall, La Grande, was elected president, Dr. W. D. McNary, Pendleton, vice-president, and Dr. T. M. Henderson, Pendleton, secretary-treasurer (reelected).

**Social Hygiene in Oregon.**—At the second annual meeting of the Oregon Hygiene Society held in Portland, October 17, Dr. Calvin S. White was elected president, Dr. William House chairman of the publication committee, Dr. Andrew C. Smith chairman of the advisory committee, and Dr. G. N. Pease chairman of the exhibit.

**State Association Meeting.**—At the thirty-ninth annual session of the Oregon State Medical Association held in Medford the following officers were elected: president, Dr. Calvin S. White, Portland; vice-presidents, Drs. R. W. Stearns and J. J. Emmons; secretary, Dr. M. B. Marcellus, Portland (reelected). Portland was selected as the next place of meeting.

### PENNSYLVANIA

**Physician Exonerated.**—A verdict exonerating Dr. Victor P. Vieslet, Charleroi, from blame in the causation of the death of John Almosi, who was struck and fatally injured by the physician's car recently, was returned by the coroner's jury, November 8.

### Philadelphia

**Medical College Buys Building.**—Jefferson Medical College has purchased for $12,000 a three-story brick building adjoining the Jefferson College Institute of Anatomy.

**Medical Staff Banqueted.**—The annual meeting of the medical staff of St. Mary's Hospital was held November 19. At the banquet which followed the meeting Dr. Ellwood R. Kirby acted as toastmaster and short addresses were delivered touching on the improvements to be made at the institution early next year at a cost of $225,000.

### SOUTH DAKOTA

**Personal.**—Dr. H. T. Ground, Aberdeen, has been appointed a member of the staff of the State Hospital for the Insane, St. Peter, Minn.——Dr. and Mrs. E. B. Taylor, Huron, sailed for Europe, November 1.

**New Hospitals.**—The new Peabody Hospital, Webster, was formally opened October 18. The building is 36 by 56 feet, and two stories and a basement in height, and has accommodation for sixteen patients.——Mitchell has been selected as the location of the new Methodist Hospital.

**New Officers.**—Black Hills Medical Association in Deadwood, November 6: president, Dr. F. E. Ashcroft, Deadwood; secretary-treasurer, Dr. F. W. Minty, Rapid City.——Third District Medical Association at Aberdeen: president, Dr. N. K. Hopkins, Arlington; secretary-treasurer, Dr. L. N. Grosvenor, Huron.

### TEXAS

**Association Changes Name.**—The Texas Antituberculosis Association will hereafter be known as the Texas Public Health Association.

**Academy of Medicine Organized.**—The San Antonio Academy of Medicine was organized November 10, and the following officers were elected: president, Dr. C. A. R. Campbell; vice-presidents, Drs. J. W. Carhart and F. Hadra, and secretary-treasurer, Dr. R. A. Roberts.

**New Officers.**—Fifth District Medical Society at San Antonio, November 6; president, Dr. William Myers, Seguin; secretary, Dr. J. A. McIntosh, San Antonio (reelected).——Fourth District (San Angelo) Medical Association at Lampasas, October 28 and 29: president, Dr. J. W. Ellis, Lampasas; secretary-treasurer, Dr. J. M. Horn, Brownwood (reelected). Ballinger was selected as the next place of meeting——Sixth District Medical Association at Corpus Christi, October 14: president, Dr. F. G. Painter, Corpus Christi; secretary-treasurer, Dr. L. J. Manhoff, Port Aransas.

**Personal.**—Dr. R. L. Vineyard, Amarillo, has been appointed house physician at the Santa Fe General Hospital, Temple.——Dr. and Mrs. H. A. Logsdon, Forth Worth, entertained the Phi Chi Medical Fraternity of Texas University, November 3.——Dr. J. P. Simonds, professor of preventive medicine in the State University, Galveston, has been appointed assistant professor of pathology in the medical department of Northwestern University, Chicago.——Dr. and Mrs. G. A. Wedemeyer, Taylor, have returned from abroad.——Dr. Milton W. McMurray suffered a fracture of two ribs and a severe sprain of the ankle in a collision between his automobile and a Frisco passenger train at Houston, October 29.

### WASHINGTON

**Personal.**—Dr. Jesse Wilbur Calkins, Seattle, has gone to Europe for three years' study.——Dr. J. M. Semple, superintendent of the Eastern Washington Hospital for the Insane, Medical Lake, has resigned to take effect November 9.

**Silver Jubilee of Society.**—The King County Medical Society celebrated its silver jubilee at Seattle with a banquet at the Arctic Club over which Dr. Arthur E. Burns presided as toastmaster. Ten of the charter members of the association were present.

**Anatomical Club Incorporated.**—Eleven physicians of Seattle have incorporated an anatomical club for the purpose of carrying on studies in surgical anatomy. The association has an arrangement with the county commissioners of King County by which the bodies of paupers will be furnished for dissection.

**New State Board Members.**—Governor Lister on November 15 announced the appointment of a new board of medical examiners. From the regular school Drs. Robert Percy Smith and Andrew J. Nelson, Seattle; Royal A. Gove, Tacoma; Jesse J. Tilton, Toppenish, and Conrad N. Suttner, Walla Walla, were appointed. Drs. James A. MacLachlan, Dayton, and Elmer D. Olmsted, Spokane, are representatives of the homeopathic school, and J. R. Walker, Sunnyside, and J. E. Hodgson, Spokane, are the osteopathic members of the board.

### WEST VIRGINIA

**Hospital Incorporated.**—The Beckley Hospital and Nurses' Training School, with accommodations for thirty patients, has been incorporated by Drs. James E. Coleman, Fayetteville, and Robert Wriston, Beckley, with a capital stock of $25,000.

**Physicians of Four Counties Meet.**—At the annual meeting of the Grant, Hampshire, Hardy and Mineral Counties Medical Society, held in Piedmont, October 16, the following officers were elected: president. Dr. Zadock T. Kalbaugh, Piedmont; secretary-treasurer, Dr. W. Holmes Yeakley, Keyser (reelected).

**Instruction of Health Officers.**—In accordance with the provisions of the county medical practice law, the State Board of Health held a meeting in Parkersburg, November 28, devoted to the instruction of county and municipal health officers in the region adjacent to Parkersburg. In the evening a public meeting was held at which Dr. A. B. Frost, U.S.P.H S., Governor Hatfield, and the president and secretary of the state board made addresses on subjects pertaining to health affairs.

**Personal.**—Dr. Joseph M. Houston, Elm Grove, was painfully injured by a fall from a horse November 10.——Dr. L. A. Davidson, West Milford, is ill and under treatment at the State Hospital, Weston.——Dr. Jonathan Edward Burns, Wheeling, has returned from Europe.——Dr. Lewis V. G. Guthrie, Huntington, has been reappointed superintendent of the West Virginia State Hospital, Huntington.——Dr. Robert A. Ashworth, Richwood, has been appointed official physician for the State Penitentiary, Moundsville, vice Dr. J. C. Peck, resigned.——Dr. John W. Gilmore, Wheeling, has been appointed a member of the medical board of the View Point Sanitarium and Ohio County Antituberculosis Dispensary, vice Dr. Thurman Gillespy.

### GENERAL

**Meeting of Alton Surgeons.**—At the annual meeting of the Chicago and Alton Railway Association of Surgeons held in Chicago, November 8, Dr. H. C. Fairbrother, East St. Louis, was selected president and Dr. J. W. Dreyfus, Louisiana, Mo., vice-president.

**Soo Line Surgeons to Meet.**—The seventh annual meeting of the Minneapolis, St. Paul and Sault Ste. Marie Railway Surgical Association will be held in Milwaukee December 4 and 5. Governor McGovern of Wisconsin will deliver an address on "The Workman's Compensation Act."

**Personal.**—Dr. A. E. Spaulding, Luverne, president of the Minnesota State Medical Association, has been elected president of the Rock Island Railway Surgeons' Association.——Dr. Henry M. Bracken, St. Paul, secretary of the Minnesota State Board of Health, has been elected president of the Minnesota School Hygiene Association.——Drs. Homer J. Hall, Franklin, Ind., has been elected a vice-president of the National Council of One-Hundred, a reform organization connected with the

Anti-Saloon League, and Dr. Thomas D. Crothers, Hartford, was elected a member of the council.

**Appropriation for Scientific Research.**—The trustees of the American Medical Association have made a new appropriation for the Committee on Scientific Research. The committee has decided to use this money as far as possible to promote work in medical research where suitable conditions exist but where such work suffers for the lack of relatively small sums of money. Applications for grants are invited and may be sent to any member of the committee, which consists of L. Hektoen, 1743 West Harrison Street, Chicago; S. Flexner, Rockefeller Institute for Medical Research, New York, and William Litterer, Vanderbilt University, Nashville, Tenn.

**Bequests and Donations.**—The following bequests and donations have recently been announced:

Mount Sinai Hospital, New York City, $100,000, one-half of the income to be used for the department of nervous diseases, and the remainder for the general purposes of the hospital; St Luke's Hospital, German Hospital and Dispensary, New York Eye and Ear Infirmary and Lincoln Hospital and Home, each $25,000 by the will of Benjamin Altman.

New York Post Graduate School and Hospital, $2,000 by the will of Mrs Mary L Parsons

Beth Israel Hospital, New York City, $5,000; Mount Sinai Hospital, $2,500; Lebanon Hospital and the Montefiore Home, each $1,500; Hospital for Deformities and Joint Diseases, Har Moriah and the National Jewish Hospital, Denver, each $1,000.

Mount Sinai Hospital, New York, German Hospital and the Montefiore Home each $2,500 by the will of Max E Bernheim

South Bend Visiting Nurses' Association, a donation of $5,000 by Mrs George W Wyman

Boston Medical Library, $86,800 by the will of Mrs. Ellen B Wyman, Newburyport, Mass., to be known as the Samuel Wheeler Wyman Memorial Fund

Charity Hospital, New Orleans, $20,000 by the will of Mrs Tilton, a donation of $1,000 from the estate of Edward Rosenberg, a second payment of equal amount to be paid Oct 1, 1914.

**Army Medical Corps Examinations.**—The surgeon general of the Army announces that preliminary examinations for appointment of first lieutenants in the Army Medical Corps will be held on Jan. 19, 1914, at points to be hereafter designated. Full information concerning these examinations can be procured on application to the "Surgeon General, U. S. Army, Washington, D. C." The essential requirements to secure an invitation are that the applicant shall be a citizen of the United States, shall be between 22 and 30 years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits and shall have had at least one year's hospital training as an intern, after graduation The examinations will be held simultaneously throughout the country at points where boards can be convened. Due consideration will be given to localities from which applications are received, in order to lessen the traveling expenses of applicants as much as possible In order to perfect all necessary arrangements for the examinations, applications must be completed and in possession of the adjutant general at least three weeks before the date of examination Early attention is therefore enjoined on all intending applicants. There are at present twenty-six vacancies in the medical corps of the Army.

## CANADA

**New Hospital.**—A new fifty-room hospital is to be erected at Walkerville, Ont, at a cost of $50,000.

**New Officers.**—Vancouver Medical Association: president, Dr. J. W. McIntosh; vice-president, Dr. W. D. Keith; secretary-treasurer, Dr. A. B. Schinbein. At the meeting November 10, Dr. Peter H. Bryce, medical officer, Department of the Interior, Ottawa, delivered an address on "The True Physician as Sociologist."

**Dissatisfaction with Examination of Schoolchildren.**—Several school trustees of the board of education, Toronto, are dissatisfied with the medical inspection of schoolchildren as carried out at present by the board of education, and will back the city council in its appeal to the Ontario government for special legislation to have the inspection done under the health department of the city.

**Personals.**—Dr. Charles A. Webster, graduate of Knox College, Toronto, and now professor of anatomy at Beirut, Syria, has terminated his furlough in Toronto and has returned to his duties in the foreign mission field of the Presbyterian Church of Canada.——Sir Arbuthnot Lane returning from Chicago, spent a day in Toronto and inspected the new General Hospital and the Wellesley private hospital Sir Arbuthnot considers the Toronto General Hospital the best he has ever seen. He visited Ottawa November 22, and sailed from Montreal for England November 29.

**Medical Inspection of Schools in British Columbia.**—The Committee on the Medical Inspection of Schools of the Canadian Medical Association at the annual meeting in London last June, reported that medical inspection of schools was further advanced in the province of British Columbia than in any other province in Canada. Dr. C. J. Fagan, secretary of the Board of Health of that province, has just reported to the provincial secretary on this work for the year ended June 30 This work has been prosecuted since 1911, has made considerable progress and is now well organized throughout that province. The whole work is under the supervision and charge of the provincial board of health and the medical inspectors in the unorganized districts are paid by that board. The work done in the cities of Victoria, New Westminster, Vancouver and South Vancouver has been excellent. When the tabulated report is inspected it is seen that there is a great number of scrofulous conditions present in the pupils. Twenty per cent. of all children reveal some sign of tuberculosis. Dr. Fagan urges the establishment of outdoor classes and outdoor schools and argues that the principle of the preventorium or open-air school should be extended so as to include all schools. In nearly all schools the teachers have heartily cooperated in the work. A report on 29,774 children shows that 16,774 are unvaccinated. All told 37,591 pupils were examined, enlarged tonsils and defective teeth giving the largest numbers: for the former, 5,302; for the latter, 12,644.

## LONDON LETTER

LONDON, Nov. 8, 1913.

### Nostrums in Australia

An address read before the Queensland branch of the British Medical Association by Dr. David Rosenburg contains some interesting information on the nostrum problem at the antipodes. In 1905 an act was passed which compelled a proper trade description of imports, including foodstuffs and patent medicines, but no restrictions were imposed with regard to articles produced in the commonwealth As a result the following ridiculous situation has arisen: A preparation was imported which was known to be harmful but which bore a misleading label stating that it was harmless, especially to children. Under the commerce act the importers were called on to amend the statements. Instead of doing so they imported the substance in bulk and printing the labels in Australia, packed and labeled the medicine in the old way and so its sale was unaffected. The customs department has prevented the importation of (1) "cure-alls" with extravagant claims and absurd prices; (2) spirits claiming vast medicinal benefits, and (3) preventives to conception. A cancer cure which was prohibited by the customs is now being made in Victoria and freely sold. "Radam's Microbe Killer" was objected to because its label declared: "It is a positive and certain cure for all diseases and is guaranteed to be perfectly harmless. It will effect a cure in every instance if given a fair trial. It is perfectly harmless, and can be taken in any quantity without danger." Dr. Rosenburg quoted the fact that analysis by the American Medical Association showed that it contained hydrochloric acid, sulphuric acid and red wine. Its importation was prohibited, with what result? It is now being made in Victoria, and the federal government has no power over the advertisements or manufacture The following are some other examples of articles, the importation of which was prohibited but which are now freely made and sold in the commonwealth: Blair's gout and rheumatic pills were prohibited because they falsely claimed to affect psoriasis and eczema, which they alleged were gouty skin affections The label of "Wioletta Hair Tonic" was objected to by the customs. In the Australasian it is advertised thus: "I'm the absolute cure for baldness." Indian Root Pills and Doan's Backache Pills, "a specific for diabetes, congestion of the kidneys, inflammation of the bladder," are being imported in bulk, and after leaving the customs are packed in Australia, and the commonwealth government has no power over them Under the commerce act the claims for medicinal benefit from alcohol are not allowed on importation. The following are some specimens of the advertisements of articles manufactured in the commonwealth: "White Horse Whiskey"—"heart tonic" Wolfe's Schnapps—"a standard tonic," and, again, "A stimulant that is medicinal in its action. and is a direct health promoter, worthy of all men drinking It has curative effect in kidney, bowel, and urinary affections" "Wincarnis," 21.4 per cent. proof spirit "Vigorous vitality and sturdy strength."

### Natives in the Medical Service of the Indian Army

In my last letter the effect of the recent throwing open of civil medical appointments in India to local practitioners, usually natives, was discussed. The medical service of the Indian Army, though open to the natives, has been mainly recruited from the British Isles. The examination is held in London and the appointments have been highly prized because the pay and other emoluments are much better than those in the British Army. The most brilliant of the recently qualified physicians have freely competed for them. The diminution of the emoluments is already producing a serious effect on the number of British candidates. At the last examination twelve vacancies were offered, and five of the successful candidates, including the first three, were Indians. It may be added that all the candidates must have British qualifications. This is not the first time that an Indian has headed the list of successful competitors. Admission to the Indian Medical Service was first thrown open for all duly qualified British subjects in 1853, and at the first competitive examination held under this act an Indian passed with the highest rank. In 1864 he was appointed professor of materia medica in the Calcutta Medical College, a post which he held until his death in 1874. Half a century elapsed before another Indian headed the list. But the obtaining of the first three places by Indians is unprecedented. That this is due not to exceptional merit of the Indian candidates but to diminished competition of the British, is indicated by the fact that the marks obtained in this competition are unusually low. In the last twelve examinations the highest marks obtained by the first man were 4,120 and the lowest 3,447. Only once have the numbers been less than on the present occasion (3,517). The marks of the twelfth man have varied from 3,554 to 2,958, whereas in the last examination they were only 2,878.

### Sugar as a Butter Preservative

An unsuccessful prosecution was brought against a Liverpool firm on the charge of selling butter containing sugar. The prosecution claimed that the 1.2 per cent. of sugar present was a foreign ingredient. According to the law sugar could be used as a preservative; but as the quantity here present was not sufficient, it must be regarded as a foreign substance. The defendant stated that sugar was put in because the public liked a mild sort of butter. The magistrate dismissed the charge as he thought the act contemplated the presence of other preservatives besides salt.

### Royal Commission on Venereal Diseases

The king has approved of the appointment of a royal commission to inquire into the subject of venereal diseases in the United Kingdom, their effects on the health of the community, and the means by which these effects can be alleviated or prevented, it being understood that no return to the policy or provisions of the contagious diseases acts is to be regarded as falling within the scope of the inquiry. These acts provided for the compulsory examination and detention of prostitutes. The public feeling aroused against them grew so much that their reintroduction in any form is out of the question. As stated in previous letters to The Journal, the appointment of this commission may be traced to the resolution passed at the International Medical Congress. It is composed of prominent public men and women, clergymen and a number of medical specialists (Sir Malcolm Morris, Sir John Collie, Dr. Mott, Mr. Ernest Lane and Mrs. Scharlieb). For a long time attempts have been made to induce the government to appoint this commission. In 1899 memorials were presented to Lord Salisbury (then prime minister) by the royal colleges of surgeons of England and Ireland and the British Medical Association, but the breaking out of the Boer War caused the subject to be shelved. In the same year the International Congress on Venereal Diseases was held at Brussels and resolutions were passed urging the various governments to appoint commissions of inquiry. The congress declared definitely against anything in the nature of the contagious diseases acts. Next a discussion on the subject took place at the Royal Society of Medicine in 1912. In June of this year Sir Malcolm Morris published an article in the *Lancet*, which received editorial support, asking for the appointment of a royal commission and drawing attention to the grave dangers of venereal disease being contracted innocently. Later a letter was published in the *Morning Post* asking for the appointment of a royal commission, signed by the presidents of the royal colleges of physicians and surgeons, the professors of medicine in the universities, and the presidents of the medical societies. This letter was endorsed by the representative meeting of the British Medical Association. A remarkable feature of the situation is the open manner in which the lay press has discussed the problem of venereal disease. During the meetings of the congress columns of the leading journals, the *Times* and *Morning Post* in particular, were devoted to discussions on syphilis. A few years ago these journals would scarcely dare to print the word and would use some periphrasis such as "a certain contagious disease."

## PARIS LETTER

*(From Our Regular Correspondent)*

Paris, Nov. 7, 1913.

### Action of Chlorids on Calomel

It is customary to warn patients who have taken calomel to refrain from salt or salted foods for some hours at least, after the medicine has been taken. Occasional complications which follow the taking of calomel have for a long time raised the question of a possible decomposition of calomel, with the formation of corrosive sublimate, in the presence of the sodium chlorids in foods. The question of the incompatibility of calomel and of table salt has been studied again recently. Dr. Patein, head pharmacist at the Lariboisière hospital, recently reported before the Académie de médecine the results of his experiments, which show that practically calomel is transformed into the sublimate by chlorids and lactates of sodium and ammonium, preformed or not, only when these salts are neutral. Decomposition begins only when the medium becomes alkaline. Sodium chlorid has the property of protecting calomel against the decomposing action of sodium carbonate. The purgative action of calomel cannot be attributed to its partial decomposition in the stomach. Patein found that dogs which had taken calomel mixed with salt showed no symptom of intoxication.

### The Red-Cross Emblem

A recent decree fixed the conditions under which the red cross on white field or the words "red cross" or "Geneva cross" may be employed when, under exceptional conditions, their commercial use is authorized. According to this decree, goods made by private persons may bear these emblems or words on the packages or wrappers only on condition that they have been manufactured on commission for public use in the army or navy or for societies officially authorized to give aid to the sanitary service of the army or for associations which are officially authorized to give aid to the wounded, the sick or the shipwrecked and which have hospital buildings provided with an official commission.

### Hygiene Among Barbers

At the last session of the Société de prophylaxie sanitaire et morale, Dr. Charles Fouquet, who had been commissioned to report on methods of diminishing the danger of infection from barbers, made the following recommendations, which are to be submitted to the barbers' organization: (1) that customers known to be sick or apparently sick should supply their own implements; (2) that the barber should wash his hands with soap and water before waiting on a customer; (3) that only clean and sterilized instruments should be used. It must be admitted that the first of these demands is unreasonable, since the barber cannot be expected to have this knowledge. For the cleaning and sterilizing of the instruments the following are the rules to be recommended: Edged tools should be washed in a 1 per cent. solution of sodium carbonate and dried; hair-brushes, shaving-brushes and combs should be cleaned every evening with water, soap and ammonia; metallic instruments should be passed through the flame; basins and shaving-brushes should be immersed in boiling water each time used; brushes and combs should be kept hermetically closed in a compartment in which stands an uncovered saucer containing a 40 per cent. dilution of liquor formaldehydi; the powder-puff should be replaced by a pad which should be thrown away after use, or by a shaker; rock alum should also be replaced by powdered alum applied with a pad; also the barber should not whet the razor on the palm of the hand.

### Organization for English-Speaking Students

A Britannic section of the Université de Paris has been founded at the Sorbonne by English-speaking students. It is intended to facilitate relations between its members and English and American men and women who are interested in the intellectual affairs of France. Foreign students from English-speaking countries are admitted on the same footing as French students. The annual fee is 4 francs (80 cents).

## Marriages

Edward Eames Holman, M.D., Pine River, Minn., to Miss Mary E. Corey of Terre Haute, Ind., at St. Paul, Minn., October 28.

William Stanley Timblin, M.D., Chicago, to Miss Frances Ray Goldsworthy of Windsor Park, Chicago, November 22.

Clyde Watkins Jump, M.D., Bozeman, Mont., to Miss Belle B. Pierce of Townsend, Mont., at Helena, November 5.

Michael Penn Cummings, M.D., Reidsville, N. C., to Miss Besse Ray Grove of Philadelphia, November 12.

George Tilman Banker, M.D., to Miss Katharine deWolfe Marble, both of Elizabeth, N. J., November 15.

Theodore Alan Willis, M.D., Clear Lake, Ia., to Miss Clara Marian Hammer of Harlan, Ia., November 4.

Rabun Thomas Wilson, M.D., Houston, Tex., to Miss Metta Inez Andrews of Abilene, Tex., November 5.

Francis Palmer Richards, M.D., to Miss Mildred Edith Burnett, both of Mackay, Idaho, October 23.

Thomas Francis Leen, M.D., to Miss Anna Jones Malley, both of Boston, at Brookline, November 11.

Harry Merton Page, M.D., Ashford, Wash., to Miss Amelia Johnson of Kelso, Wash., October 19.

Eugene A. MacCornack, M.D., Chicago, to Miss Harriet L. Hiebner of Glencoe, Ill., September 5.

Harvey P. Matthews, M.D., to Miss Emma L. Grennell, both of Brooklyn, November 11.

Joseph D. Ely, M.D., Hudson, Mich., to Mrs. Ellen Van Buskirk of Fayette, O., November 8.

Harper Lane Proctor, M.D., to Miss Sara Maude Gross, both of Jacksonville, Fla.

W. H. Grainger, M.D., to Miss Jessie Costa, both of East Boston, November 12.

## Deaths

**John T. McAnally, M.D.** Northwestern University Medical School, 1883; a Fellow of the American Medical Association; of Carbondale, Ill.; formerly mayor of that city; for two terms a member of the Illinois State Board of Charities; at one time president of the Illinois State Medical Society, councilor of the Ninth Illinois District, and a member of the House of Delegates of the American Medical Association; one of the best known practitioners of Southern Illinois; died in the Presbyterian Hospital, Chicago, November 19, aged 65.

**John Brown Gaston, M.D.** University of Pennsylvania, Philadelphia, 1855; a member of the Medical Association of the State of Alabama; surgeon of the Nineteenth Alabama Regiment, C.S.A., and later division surgeon during the Civil War; twice mayor of Montgomery and since 1895 probate judge; a prominent and beloved citizen of Montgomery; died at the home of his son, November 8, aged 79.

**John G. Daniels, M.D.** University of Louisville, Ky., 1877; health officer of Upshur County, Texas; a member and secretary of the Board of Medical Examiners for the Seventh Judicial District of Texas from 1888 to 1901; local surgeon of the St. Louis and Southwestern Railway since 1883; died at his home in Gilmer, October 30, aged 60.

**William Royal Engel, M.D.** Jefferson Medical College, 1906; formerly physician in charge of the Thermal Belt Sanatorium, Tryon, N. C., and of the North Carolina Tuberculosis Sanatorium, Montrose, and since 1911 a practitioner of Charlotte, N. C.; died at his old home in Tryon, October 28, from tuberculosis, aged 35.

**Rudolph Clarence Mollman, M.D.** University of Pennsylvania, Philadelphia, 1900; of Reading, Pa.; died at Longport, Atlantic City, N. J., November 5, from the effects of a gunshot wound believed to have been self-inflicted with suicidal intent, while despondent on account of ill health, aged 37.

**C. W. Theodore H. Buehring, M.D.** University of Göttingen, Germany, 1892; formerly of Nordheim, Texas; local surgeon of the San Antonio and Aransas Pass Railroad; a member of the American Association of Life Insurance Examining Surgeons; died at his home in Lockhart, Texas, November 4, aged 39.

**Gurley Davis Moose, M.D.** University of Maryland, Baltimore, 1907; of Mount Pleasant, N. C.; a Fellow of the American Medical Association; who contracted tuberculosis while an intern in Johns Hopkins Hospital; died from that disease in a hospital in Asheville, N. C., November 7, aged 30.

**Thomas James, Jr., M.D.** Hospital College of Medicine, Louisville, 1901; was found dead in his office in Louisville, October 22, from the effects of a bullet wound of the right temple, believed to have been self-inflicted with suicidal intent, while despondent on account of ill health, aged 35.

**Allen M. Hall,** Pennsylvania University, Lexington, Ky., 1848; chief surgeon of the Eighth Tennessee Infantry, C.S.A., during the Civil War; a practitioner of Sumner and Shelby counties, Tenn., for many years; died at the home of his daughter in Memphis, October 28, aged 90.

**Samuel B. Mills, M.D.** University of Louisville, 1852; for several years teacher of physiology and hygiene in the Louisville schools; at one time a member of the Board of Health; died at the home of his daughter in Fostoria, Louisville, October 24, from senile debility, aged 85.

**Thomas Constantine Finnell, M.D.** New York University, New York City, 1880; acting assistant surgeon, U. S. Army, during the Spanish-American War; physician for the Board of Health and Board of Education, New York City; died suddenly, November 6, aged 54.

**Fred J. Peterson, M.D.** California Eclectic Medical College, Los Angeles, 1900; died at his home in Camp Meeker, Cal., September 9, from the effects of a gunshot wound believed to have been self-inflicted with suicidal intent, while despondent on account of ill health.

**George W. Campbell, M.D.** College of Medicine of Southern California, Los Angeles, 1889; formerly a member of the city council of Los Angeles and coroner of Los Angeles County; a pioneer of Boyle Heights; died in the Clara Barton Hospital, Los Angeles, October 27.

**William Lloyd Richards, M.D.** University of Pennsylvania, Philadelphia, 1896; formerly a member of the American Medical Association; a member of the Medical Society of the State of Pennsylvania; died at his home in Wilkes-Barre, November 6, aged 39.

**Philip T. O'Brien, M.D.** Albany (N. Y.) Medical College, 1872; for several years a member of the board of selectmen and the town school committee of Plymouth, Mass.; died at his home in Plymouth, October 31, from cerebral hemorrhage, aged 64.

**George Alton Kennedy, M.D.** University of Toronto, Ont., 1878; of Macleod, Alta.; surgeon-captain in the Northwest Mounted Police and local surgeon of the Canadian Pacific System; died in the Winnipeg General Hospital, October 8, aged 55.

**Rudolph Ravenburg, M.D.** George Washington University, Washington, D. C., 1874; a veteran of the Civil War; for half a century an employee of the War Department, Washington, D. C.; died in his apartment in that city, October 23, aged 81.

**Thomas Benjamin Amiss, M.D.** University of Pennsylvania, Philadelphia, 1861; a member of the Medical Society of Virginia and a surgeon in the Confederate service throughout the Civil War; died at his home in Luray, November 9, aged 74.

**John Palmer Birch, M.D.** Hahnemann Medical College, Philadelphia, 1870; for several years a member of the West Philadelphia School Board; died in the Hahnemann Hospital, Philadelphia, October 31, after a surgical operation, aged 81.

**David K. Stringer, M.D.** College of Physicians and Surgeons, Keokuk, Iowa, 1880; a practitioner of Grundy and Sullivan counties for forty-six years; died at the home of his daughter in Trenton, Mo., November 11, from cirrhosis of the liver.

**Elizabeth G. Pyrum-Perry, M.D.** Eclectic Medical College of the City of New York, 1882; a practitioner of New York City until 1892 and thereafter a resident of Fryeburg Center, Me.; died in that place, November 7, from pneumonia, aged 93.

**Walter Lowry Williams, M.D.** New York University, New York City, 1872; a member of the Medical Society of the State of Pennsylvania; local surgeon for the Pennsylvania System at Ridgway; died at his home, November 8, aged 69.

**Bennie Castleman, M.D.** University of Nashville, 1910; of Gladeville, Tenn.; died in St. Thomas' Hospital, Nashville, October 1, six days after an operation for appendicitis, aged 33.

**Charles Edward Feller, M.D.** Rush Medical College, 1885; of St. Paul, Minn.; died in St. Joseph's Hospital in that city, October 31, from stricture of the esophagus, aged 58.

**John Tidwell Nethery, M.D.** Vanderbilt University, Nashville, Tenn., 1891; a practitioner of Gibson County, Tenn., for more than thirty years; died at his home in Caruthersville, Mo., October 23, from cerebral hemorrhage, aged 61.

**Daniel D. Kreider, M.D.** Medico-Chirurgical College, Philadelphia, 1911; a Fellow of the American Medical Association and president of the Board of Health of Mount Holly Springs, Pa.; died at his home, November 7, aged 30.

**Thomas E. Casterline** (license, Nebraska, 1891); a practitioner for more than forty-five years; a veteran of the Civil War; one of the proprietors of the Edgar *Sun*; died at his home in Edgar, Neb., October 21, aged 87.

**Wilson A. Long, M.D.** College of Physicians and Surgeons, Baltimore, 1882; of Frederick; a member of the Medical and Chirurgical Faculty of Maryland; died in St. Agnes' Hospital, Baltimore, November 7, from pneumonia.

**James Fleming McCarrell** (license, Washington County, Pa, 1881, Allegheny County, Pa., 1890); a practitioner since 1868; died at the home of his brother in Dinsmore, October 31, from pneumonia following a fall, aged 81.

**Harry A. Smith, M.D.** University of Southern California, Los Angeles, 1894; for some time physician at the Whittier State School; died in his office in Los Angeles, November 2, from internal hemorrhage, aged 40.

**Bryant Hopkins Nowlin, M.D.** Bellevue Hospital Medical College, 1873; Louisville Medical College, 1886; a Confederate veteran; of Iola, Texas; died at the home of his daughter in Teague, Texas, August 9, aged 72.

**George Thomas Mason, M.D.** College of Physicians and Surgeons, Keokuk, Iowa, 1892; of Mount Pleasant, Iowa; for two terms auditor of Henry County; died at his home, November 4, aged 62, from nephritis.

**Samuel Bell Bunch, M.D.** University of Nashville, Tenn., 1889; of New Roe, Ky.; was found dead near his home October 26, from the effects of an accidental gunshot wound of the chest, aged 59.

**John H. Howard** (license, Tennessee, 1899); in practice for more than fifty years; a Confederate veteran; died at his home in Lexington, September 7, from hemorrhage of the stomach, aged 81.

**Edward C. Lemen, M.D.** Washington University, St. Louis, 1868; for forty years a practitioner of Alton, Ill.; a veteran of the Civil War; died in a sanatorium in Jacksonville, November 9, aged 72.

**D. D. Potter, M.D.** College of Physicians and Surgeons, Keokuk, Iowa, 1883; of Seward, Neb.; died at the home of his brother in Mount Hope, Kan., November 4, from tuberculosis.

**Durand Hatch Albright, M.D.** Jefferson Medical College, 1851; one of the oldest practitioners of Alamance County, N. C.; died at his home near Snow Camp, November 3, from cerebral hemorrhage.

**Charles Edgar Wilson, M.D.** Medical School of Maine, Brunswick, 1885; a member of the Maine Medical Association; died at his home in East Hiram, November 4, from heart disease, aged 60.

**Samuel Augustus Marlin, M.D.** Western Pennsylvania Medical College, Pittsburgh, 1894; of Clinton, Pa.; was killed in an automobile accident near Stoop's Ferry, Pa., October 23, aged 50.

**Daniel A. Arter** (license, Westmoreland County, Pa., twenty years' practice, 1881); a practitioner since 1850; died at his home in Canton, Ohio, November 5, from senile debility, aged 85.

**James C. Johnson, M.D.** Atlanta (Ga.) Medical College, 1859; for many years a practitioner of Macon, Ga.; died at his home in Vineville, November 1, from senile debility, aged 75.

**James S. Baugh, M.D.** Trinity Medical College, Toronto, Ont., 1881; medallist of his class; died suddenly at his home in Hamilton, Ont, October 18, from heart disease, aged 63.

**John Kuestner, M.D.** Hahnemann Medical College, Philadelphia, 1887; of Philadelphia; died in the Pennsylvania Hospital for the Insane, October 20, from strangulation by food.

**Frank Marion Davis, M.D.** Ohio Medical University, Columbus, 1901; a Fellow of the American Medical Association; died at his home in Pittsburgh, November 7, aged 44.

**Charles Lingham Cunningham** (license, Maryland); a practitioner for more than twenty-five years; died at his home in Cresaptown, October 22, from nephritis, aged 51.

**George W. Armentrout, M.D.** College of Physicians and Surgeons, Keokuk, Iowa, 1899; died at his home in Letts, Iowa, November 2, from heart disease, aged 50.

**Ivan Annett, M.D.** Western University, London, Ont., 1911; of Windsor, Ont.; died in Victoria Hospital, London, Ont., October 5, after a surgical operation, aged 23.

**Camillus B. Faulconer, M.D.** St. Louis Medical College 1865; a physician and capitalist of Montgomery, Mo.; died at his home, August 31, from nephritis, aged 78.

**William W. Hill, M.D.** Toledo (Ohio) Medical College, 1883; a veteran of the Civil War; died at his home in Weston, Ohio, October 17, from arteriosclerosis, aged 66.

**William A. Hawk, M.D.** Jefferson Medical College, 1880; a physician and pharmacist of Tower City, Pa.; died at his home, October 24, from heart disease, aged 50.

**Edward Horan, M.D.** Queen's University, Belfast, Ireland, 1880; of San Francisco; died in Trinity Hospital in that city, October 25, from pneumonia, aged 59.

**James B. Crucial** (license, years of practice, North Dakota); known as James Buchanan Cross; died in the Cass County Hospital, Fargo, October 30, aged 84.

**Thomas D. Gamble, M.D.** Washington University, St. Louis, 1858; of Wheatland, Iowa; died at the home of his daughter in that place, November 7, aged 83.

**John Martin Cameron, M.D.** Victoria University, Coburg, Ont., 1887; formerly of Thessalon, Ont.; died at his home in North Yakima, Wash., October 29.

**A. E. Smith, M.D.** Starling Medical College, Columbus, O., 1883; of Bracken County, Ky.; died at the home of his aunt in Cincinnati, October 14, aged 56.

**Peter Fisher** (license, years of practice, Illinois, 1878); for fifty years a practitioner; died at his home in Edwardsville, October 29, from uremia, aged 74.

**Francis M. Cullum** (license, Arkansas, 1908); an eclectic practitioner of Hartman; fell into a well at his home, November 3, and was drowned, aged 50.

**Neill Monroe Culbreth, M.D.** University of Tennessee, Nashville, 1882; died at his home in Wilmington, N. C., September 1, from spinal disease, aged 63.

**Leonadus A. Rutherford, M.D.** Eclectic Medical College of the City of New York, 1877; died at his home in Kinston, N. C., October 23, aged 63.

**David O. Munsey, M.D.** Medical College of Ohio, Cincinnati, 1878; a veteran of the Civil War; died at his home in Gaston, Ind., October 30, aged 68.

**Allan B. Carscallen, M.D.** Queen's University, Kingston, Ont., 1875; died at his home in Enterprise, Ont., recently from cerebral hemorrhage.

**Arthur Harris Davis, M.D.** University of Nashville, Tenn., 1879; died at his home in Little Rock, August 27, from heart disease, aged 53.

## PULMONOL

### Another Fraudulent Consumption Cure

"Fifty thousand physicians and all standard text-books endorse every ingredient in Pulmonol." Yes, and a hundred thousand physicians and standard text-books endorse every ingredient in dishwater; soap is good, grease is good, water is good, each in its place; but neither physicians nor any one else recommend dishwater as a cure for consumption. Neither does any physician nor any layman, except he be a fool or a knave, recommend Pulmonol as a cure for consumption.

Pulmonol is put on the market by the Pulmonol Chemical Company, New York City. The Pulmonol Chemical Company seems to be a trade name assumed by one Arthur Vincent Payne, M.D., who terms himself "medical director."

Like all consumption cures, the stuff is pushed by means of lying claims and worthless testimonials. Like every other concern that exploits "cures" for consumption, the Pulmonol Company seems to find it more natural to lie than to tell the truth when describing its panacea. In the advertising pamphlet sent out to boards of health and tuberculosis societies, Arthur V. Payne, M.D., makes this statement:

> "Many eminent and broad-minded physicians prescribe Pulmonol and use it in their private practice as their own product . . ."

Of course this is a falsehood and its author knows it is a falsehood, but apparently he expects to "get away with it." In another booklet the concern says:

> "We spent a year trying to get the doctors to use Pulmonol and finally had to give up the job."

Of the various claims made for this stuff, these are typical:

> "It cleans out the lungs."
> "Stops night sweats."
> "Prevents hemorrhages."
> "Strengthens the heart."
> "Gives strength to resist disease."
> "Cures the most stubborn coughs."

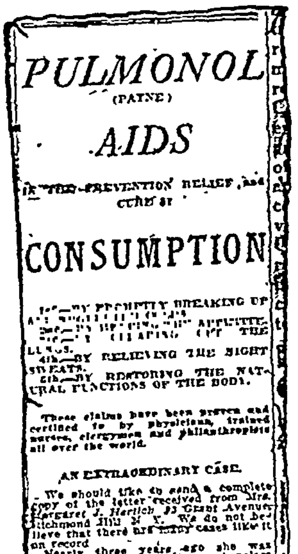
Like some other men in the consumption-cure business, A. V. Payne is shrewd enough to recommend, in his advertising matter, that those taking Pulmonol shall follow the rules laid down by reputable physicians for the treatment of tuberculosis; that, in addition to taking his nostrum, they shall live in the open air as much as possible, eat nourishing food and in other ways follow out the approved method of treating the disease. Such suggestions, coming from "patent medicine" exploiters are worthless, as every physician knows. The one reason, above all others, that causes the consumptive to fly to the quack is his belief, born of ignorance and the optimism that characterizes the disease, that the medicine he buys will relieve him of the necessity of following the strict regimen laid down by his physician.

There is an inborn belief amoung the laity that there is a specific drug for every disease—if the medical profession were only wise enough to discover it. The quack, either inferentially or directly, assures the public that he *has* found the specific; and the public believes him! It is the universal experience of those who have had much to do with consumptives that dietetic and hygienic measures are disregarded in direct proportion to the amount of medicine the sufferer takes. Herein lies the viciousness of the consumption cure. A. V. Payne may smugly "point with pride" to his "literature," in which he urges those who buy his nostrum to follow the rules laid down by scientific men in the treatment of tuberculosis, but he knows, unless he is more fool than knave, which we doubt, that such rules will not be followed, once the victim begins relying on Pulmonol.

#### SOME TESTIMONIALS INVESTIGATED

A few of the testimonials published by the Pulmonol Chemical Company have been investigated with the usual results. The testimonial-givers are, as always, divided into two classes; those who really had tuberculosis and those who did not have it. As we have said many times, it is useless to investigate fresh testimonials. Most of them are written in good faith and not until the cases have progressed further are the victims undeceived as to the efficiency of the nostrum. It is therefore necessary to wait a year or two before looking into testimonials of this class. We then find, invariably, that the consumptive who had relied on the nostrum is dead. This is what has been found in the case of Pulmonol testimonials.

One testimonial published by the Pulmonol concern was featured as an "Extraordinary Case." "We do not believe that there are many cases like it on record," says the booklet, which, after giving the testimonial, suggests that "The Committee on Tuberculosis will find this a most interesting case for its investigation." It will! The poor woman whose case is described therein has been dead for some years, and we have evidence that indicates that the Pulmonol Company continued to publish the testimonial not only after the death of the victim, but after that death had been specificially brought to the attention of A. V. Payne. A nice, ghoulish sort of business!



PULMONOL
(PAYNE)
AIDS
IN THE PREVENTION RELIEF AND CURE OF
CONSUMPTION

1st—BY PROMPTLY BREAKING UP [illegible]
2nd—BY [illegible] APPETITE.
3rd—BY CLEARING OF THE LUNGS.
4th—BY RELIEVING THE NIGHT SWEATS.
5th—BY RESTORING THE NATURAL FUNCTIONS OF THE BODY.

These claims have been proven and certified to by physicians, trained nurses, clergymen and philanthropists all over the world.

AN EXTRAORDINARY CASE.

We should like to send a complete copy of the letter received from Mrs. Margaret J. Herlich, 93 Grant Avenue, Richmond Hill, N. Y. We do not believe that there are many cases like it on record.

Nearly three years ago she was brought from Liberty, N. Y., a hopeless physical wreck. To use her own words as per her letter:

"I came back (from Liberty, N. Y.) more dead than alive. It was impossible for me to walk without assistance. I coughed, had night sweats, no appetite and lost seventy-five pounds. This was my condition after everything possible had been done, as we supposed. My daughter purchased a bottle of Pulmonol, and I commenced to take it that very night. I have taken it ever since, [illegible]

PULMONOL (Payne)
For Sale at All
Riker Drug Stores
Where Booklets Containing Further Information May Be Had

Fig. 1.—Photographic reproduction (reduced) of a typical Pulmonol newspaper advertisement. The woman whose testimonial appears in this advertisement died of consumption months before the advertisement appeared!

Another testimonial, published under the heading, "Unbiased Physician Recommends Pulmonol," was that purporting to come from a Brooklyn physician, who is alleged to have recommended Pulmonol to a tuberculous patient who was so nearly dead "that the priest was called in and the last rites were administered." The man took Pulmonol, says the booklet, "and is still taking it. He is not entirely well, but well enough to be one of the happiest men in Brooklyn." Not so; the poor fellow may be happy, but he is not in Brooklyn. He went the way of all consumptives who have reached the last stages of the disease.

Here are some other cases: Mrs. F. A. C—— testifies that she took seventeen bottles of Pulmonol "and was greatly benefited." This testimonial appears in a booklet entitled, "Fighting the White Plague, or Consumption, with Pulmonol." The inference, naturally, is that Mrs. F. A. C—— had been cured of consumption by the use of Pulmonol. The case was investigated and Mrs. C—— was found to be a strong, robust woman whose case had never been diagnosed as tuberculosis, but who just "knows she had it" because she coughed a great deal! And on such testimony as this is this wretched fraud sold to the consumptive.

In the same booklet Mrs. E. J. S—— says that her husband had "lung trouble." "He took six bottles of Pulmonol and it cured him." Here again, we note that no direct statement is made that the man has been cured of tuberculosis; but the inference is there. Investigation shows that Mr. E. J. S——, who is living and well, never had tuberculosis.

Mr. L. E. F—— also gives a testimonial that, inferentially, gives the impression that Pulmonol has cured him of consumption. Our investigation, however, shows that such is not the case, for poor F—— was one of those who really had tuberculosis. He is now dead.

Mr. S—— is alleged to have testified that he was afflicted with tuberculosis and had "consulted the best physicians." He tried sanatorium treatment, but in spite of all continued to get worse. Finally he "bought a bottle of Pulmonol" and "took the medicine as a joke." As a result he alleges: "I am now relieved of all distressing symptoms and gaining in weight and strength daily—and attending to business." This case was investigated with some care and the physicians under whose treatment he claims to have been at the sanatorium were written to for a history of the case. We found that Mr. S—— died of tuberculosis some time ago.

A testimonial dated from a village of less than 1,300 population and alleged to have been written by a Mrs. A. O. B——, urges "every one suffering with consumption" to take Pulmonol as she had done. A physician who lives and practices in this village was written to regarding this case, the full name of the alleged testimonial writer being given. He replied that, although he had lived in the place more than ten years, he had never heard of such a person.

Mrs. C. D. W—— is another individual whose name is given in the testimonial list. On making inquiries, we discovered that Mrs. W—— did have tuberculosis and still has it. She is not taking Pulmonol at present. Her physician says, "Her health is somewhat better than it was a few years ago," and he adds: "I do not consider her improvement due to Pulmonol."

Mr. L. S——, the Pulmonol concern would have the public believe, was cured of tuberculosis by the use of its nostrum. We find, on looking into the matter, that Mr. S—— had tuberculosis some five years ago and that he went to the state sanatorium for treatment. He returned much better. His family physician writes us that he regards this "as an arrested case, produced by sanatorium treatment."

The same old story: the individuals that really suffered from consumption and relied on the "consumption cure" are dead. Every testimonial for a "consumption cure" that we have investigated—and they number hundreds—brings out the same facts: In those cases in which the individuals are still living, they either did not have consumption, or the arrest of the disease was due to scientific treatment and not to the nostrum for which they had testified.

PULMONOL CHEMICAL CO.
NEW YORK.

Fig. 2.—The Pulmonol label.

WHAT IS PULMONOL?

Pulmonol has been analyzed in the Association's laboratory and, as is the case with most nostrums, has been found to contain drugs that have been used for years by reputable physicians. And yet Arthur Vincent Payne, M.D., yclept the Pulmonol Chemical Company, has the effrontery to declare that Pulmonol is a prescription that he has perfected after he had "given his entire life to a study of tuberculosis and diseases of the lungs." Essentially, Pulmonol consists of a mixture of benzoate of soda, a guaiacol compound, with a dash of strychnin, dissolved in a mixture of glycerin and water. Here is the chemist's report:

> "Three original bottles of 'Pulmonol' (manufactured by the Pulmonol Chemical Company, New York) were received at the Association's laboratory and subjected to chemical analysis. The bottles contained a red, aqueous liquid, having a bitter taste and a faint odor of benzoic acid. Its specific gravity was 1.088.
>
> "Qualitatively Pulmonol contained potassium, sodium, benzoate, sulphonate, glycerin, guaiacol (or cresol), strychnin and coloring matter. The red coloring matter responded to tests for the dye known as bordeaux. The guaiacol was present in a combined form and its characteristic odor became apparent only after boiling with strong sulphuric acid. The strychnin was probably present as the sulphate, as a very faint trace of sulphate was detected.
>
> "Quantitatively the mixture closely corresponded to the following:

| | | |
|---|---|---|
| Potassium guaiacol sulphonate | 5.7 | per cent. |
| Sodium benzoate | 2.1 | per cent. |
| Strychnin sulphate | 0.008 | per cent. |
| Glycerin | 11.6 | per cent. |
| Water | 77.7 | per cent. |
| Difference | 2.8 | per cent. |

Each fluidounce of Pulmonol is equivalent to approximately 29 grains of potassium guaiacol sulphonate, 10 grains sodium benzoate and 1-24 grain strychnin sulphate.

SUMMARY

To sum up: Pulmonol, exploited as a cure for consumption, is a vicious and wicked fraud. Only physicians know the enormous amount of harm done by men of the A. V. Payne type. Those who are conducting a campaign of public enlightenment on the subject of tuberculosis know how difficult it is to eradicate from the public mind the old, pernicious idea that drugs will cure consumption. Those who are selling fraudulent "consumption cures"—and there are no "consumption cures" of the drug type that are not fraudulent—undo, by their lying claims, in a few minutes the good that it has taken weeks and possibly months to attain.

It is the universal experience of visiting nurses and others who come in daily contact with consumptives that just as soon as the victim begins to rely on a widely advertised "cure," he immediately becomes careless of the safety of others and relaxes those efforts which are necessary if he hopes to overcome the disease. It is but human that such should be the case. The tendency is to follow the line of least resistance. If consumption can be cured by taking something out of a bottle four times a day, why should the sufferer subject himself to the minor inconveniences of the more or less strict regimen laid down by the physician?

Of all mean businesses in the world, there are few, if any, more contemptible, more heartless or more economically vicious, than that carried on by the man who enriches himself at the expense of the life of the unfortunate consumptive. Of all tainted money, none is quite so dirty as the blood-toll collected by the "consumption cure" faker.

## "Red Not a Satisfactory Danger-Signal"

*To the Editor:*—From an editorial with this title (The Journal, Nov. 8, 1913, p. 1724), I quote: "Just why it was selected as a danger-warning is a question for the anthropologist and historian to determine." I am not an anthropologist or a historian, but simply an eye-specialist. There is one very good reason why red has been selected as the danger-signal. Red is the one color, outside of the ordinary white or yellow light, that is seen at a great distance. At sea the first light to be seen on an approaching vessel is her white masthead light, next her port red light, and some time later her starboard green light. The substitution of yellow for one of the colors would be impossible, as it would be confused with every window- and street-light in town. There is no other unmistakable color that can be seen at so great a distance as red. Color-blind persons should not be entrusted with the navigation of ships or the operation of railway-trains.

Frank W. Edmonds, M.D., Berkeley, Cal.

## The Suicide-Rate of San Diego

*To the Editor:*—In the editorial on "Anomalies of Suicide," The Journal, Nov. 8, 1913, p. 1721, the suicide-rate for the city of San Diego, according to the statisticians, is given as "more than 40" per hundred thousand. Calculations are made, of course, on the basis of the census enumeration of 1910, which gives the official population of the city as 39,578. The census here was very poorly taken, and it was notorious that this estimate was far below the population at the time it was taken. Tents were even erected by private citizens to endeavor to obtain the registration of those who had been neglected by the enumerators. The population of the city as estimated by the compilers of the city directory in the different years, and by the number of water consumers, has been estimated by the Board of Health as follows. The city has doubled in population within the last five years owing to its approaching exposition, Jan. 1 to Dec. 31, 1915, and the construction of the railway to Yuma, now under way. Appended to the population numbers are the suicides for the year.

| Year | Suicides | Population |
|---|---|---|
| 1908 | 11 | 42,500 |
| 1909 | 12 | 45,000 |
| *1910* | 9 | 45,000 |
| 1911 | 20 | 55,000 |
| 1912 | 16 | 65,000 |
| 1913 | 23 | 85,000 |

There have been nineteen suicides to October 31, and on this basis twenty-three have been estimated for the year.

Average population for six years, 56,250.

Suicides: total, 91; average, 15.16 per annum.

Rate per hundred thousand, 26.95.

Francis H. Mead, M.D., San Diego, Cal.

## *Queries and Minor Notes*

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

### THE HARLOW-HAYHURST BLOOD-STAIN

*To the Editor:*—About two or three years ago there appeared in The Journal an article on the use of a certain blood-stain. This stain consisted of two solutions, one of eosin in methyl alcohol and the other methylene blue in methyl alcohol. The directions were to dip the slide in Solution 1 for twenty seconds and then without washing into Solution 2 for twenty seconds. I used this stain with great satisfaction, but when I had used it up I was unable to procure a fresh supply. Can you furnish me the formula?

J. Bennett Townsend, M.D., Anderson, S. C.

Answer.—Other correspondents have inquired regarding the composition and method of use of this blood-stain. The Harlow stain is discussed by W. P. Harlow in the *American Journal of the Medical Sciences*, 1904, cxxvii, 662, and in The Journal, March 6, 1909, p. 768; while the Hayhurst modification is fully described by E. R. Hayhurst in The Journal, Dec. 4, 1909, p. 1909. For the use of our readers we give, herewith, a brief description of this stain.

*Preparation of Stains:* Dissolve 0.5 gm. of eosin (Grübler's water-soluble) in 50 c.c. of absolute methyl alcohol (Merck's highest purity), and place in a 3-ounce wide-mouthed bottle. Keep bottle tightly stoppered.

Dissolve 0.5 gm. of methylene blue (Ehrlich's medicinal) in 50 c.c. of absolute methyl alcohol and place in a bottle similar to the preceding.

*Technic of Staining:* Prepare smears of the blood on slides or cover-glasses in the usual manner.

Drop the smear, air-dried but without other fixation, into the bottle containing the eosin stain and allow to remain for twenty seconds.

Remove, drain an instant against the mouth of the bottle and drop the smear directly (without washing) into the methylene blue stain for twenty seconds.

Remove, drain as before, wash rapidly to and fro (three or four quick swashes) in a tumbler of water, shake off the excess of water and dry between filter-paper. Examine with the immersion lens.

The properly stained slide should have a pink-red appearance. The carrying over of a small amount of the eosin solution into the methylene blue solution during the staining process seems to prevent deterioration of the stain by age (when the stain is used only every few days), owing to the neutralization of the excess of alkali (in the blue) by the acid eosin solution. If the stain is frequently used, it may need correcting to overcome defects in its staining properties. If the stained smear shows little or no blue coloration, add a drop of 20 per cent. sodium or potassium hydroxid to the stock methylene blue solution; while a drop of glacial acetic acid should be added, provided the stained smear appears too blue (the red cells being purple). In this way the activity of the stain may be kept constantly under control.

Used in this manner and corrected as described, the Harlow-Hayhurst stain is fairly panoptic, and is simple, convenient and dependable for routine blood-work.

### BIOGRAPHIC SKETCHES AND WORKS ON BLOOD-PRESSURE

*To the Editor:*—Please tell me where I may find satisfactory sketches of (1) Koch; (2) Pasteur; (3) Ehrlich, and (4) Jenner; and furnish me a list of the recent more or less comprehensive works on (5) blood-pressure.

M. S. Davie, M.D., Dothan, Ala.

Answer.—The following books and articles may be consulted:

1. Wezel, Karl: Robert Koch, eine biographische Studie, Berlin, August Hirschwald, 1912.
   Ford, W. W.: Life and Work of Robert Koch, *Bull. Johns Hopkins Hosp.*, December, 1911.

### HAINES' SOLUTION

*To the Editor:*—About a year ago last winter we found a formula in The Journal for the sugar test in urine. This test was to be used in place of Fehling's. We have found it more sensitive and more stable than Fehling's, but have lost the formula. Please give the formula.

H. A. Davis, M.D., Dickinson, N. Dak.

Answer.—We believe that the solution referred to is Haines' solution. The composition of this solution is as follows:

| | |
|---|---|
| Copper sulphate | 12 gm. |
| Potassium hydroxid | 45 gm. |
| Glycerin | 90 c.c. |
| Water | q. s. ad 1,000 c.c. |

This forms a clear, transparent, dark-blue liquid. Four or five c.c. are placed in a test-tube and gently boiled. Six drops of the suspected urine are added and the upper portion of the mixture brought to a boil and immediately removed from the flame. If sugar is present an abundant yellow or yellowish-red precipitate is thrown down; if no such precipitate occurs sugar is absent. The precautions to be observed in using this test are never to add at the outside more than 10 drops of urine and not to boil the mixture for more than one or two seconds after the addition of urine.

### TREATMENT OF INDICANURIA

*To the Editor:*—Please answer the following queries:

1. How would you permanently cure a marked indicanuria in a young man which has been persisting for the last five years?
2. Would you resort to the lactic acid bacillus treatment of Metchnikoff?
3. If so, which is the most reliable preparation?
4. What would result if this condition were left untreated?

X. Y. Z., New York.

Answer.—1. The presence of indican in the urine depends on putrefaction in the intestine. The process of putrefaction may be dependent on various factors. Therefore, in order to secure a permanent cure of indicanuria, we must remove the causative factors. For this purpose the bowel should be emptied and regular bowel movements secured. Inflammation of the intestine should be allayed and a diet which does not readily putrefy should be given. The diet should be mainly carbohydrate. The entire exclusion of protein for a short time at the beginning of the treatment may be advisable.

2. It is doubtful if this treatment would do any good, but it might be worth trying.

3. A number of preparations are put on the market by reliable firms, any of which may be depended on if fresh.

There are a number mentioned in New and Nonofficial Remedies. It should be remembered that the administration of lactic acid germs should always be accompanied with carbohydrate food from which the germs can form the necessary lactic food.

4. Many pathologists believe that a considerable number of internal diseases are due to the absorption of poisonous material from the intestine. It is very probable that other poisons than indican are formed in the process of putrefaction, and it is probable that these poisons have much more serious effects than indican or indol.

### BASS AND WATKINS TEST—THE HERMAN-PERUTZ TEST

*To the Editor:*—1. Please describe the Bass and Watkins rapid Widal test.

2. Please give the Herman-Perutz test for syphilis, and state whether it is reliable.

M. B. McCausland, M.D., Imlay City, Mich.

Answer.—1. The Bass and Watkins method is published in text-books on clinical diagnosis. Reference may be made to Webster's "Diagnostic Methods," p. 588.

2. The Herman-Perutz method is described in The Journal, Feb. 18, 1911, p. 547, in an abstract of the original article in the *Medizinische Klinik*, Jan. 8, 1911. In a recent article by J. Kallos (*Deutsch. med. Wchnschr.*, Sept. 25, 1913, p. 1885), the direction is given not to let the mixture of serum and reagent stand more than twenty hours. The test seems to give reactions very similar to those of the Wassermann test, but in secondary syphilis it does not give a positive reaction so frequently. It should be used only as confirmatory to the Wassermann reaction.

### ORGANISM OF WHOOPING-COUGH—FAVORITE METHOD FOR INJECTING SALVARSAN

*To the Editor:*—1. Has a specific organism been isolated for whooping-cough?

2. Which method is most in favor, the intravenous or the intramuscular injection of salvarsan?

P. E. Lineback, M.D., Anaconda, Mont.

Answer.—1. Such an organism was isolated by Bordet and Gengou a few years ago and is known as the Bordet-Gengou bacillus of pertussis. The following references may be consulted:

Bordet: The Microbe of Pertussis, *Brit. Med. Jour.*, Oct. 9, 1909.
Wollstein, M.: Bordet-Gengou Bacillus of Pertussis, *Jour. Exper. Med.*, January, 1909.
Mallory, F. B., and Hornor, A. A.: Pertussis: Histologic Lesion in Respiratory Tract, *Jour. Med. Research*, November, 1912.
Mallory, F. B.; Hornor, A. A., and Henderson, F. F.: Relation of Bordet-Gengou Bacillus to Lesions of Pertussis, *Jour. Med. Research*, March, 1913.

2. From a general view of the situation we should be inclined to say that the intravenous method has by far more adherents than the intramuscular in the injection of salvarsan. No definite statistics as to which method is most in favor are available.

### DEATHS FROM EATING CHESTNUTS

*To the Editor:*—The newspapers recently contained a report of the death of a woman from poisoning by eating chestnuts. Please explain how chestnuts can be poisonous. S. T. A.

Answer.—We have communicated with the Bureau of Plant Industry in reference to this question, and have received the following statement: "It is true that deaths have occurred in the region where the chestnut blight is prevalent, and that the chestnuts from these trees have been eaten by the patients. Further than that we have now no definite information. The matter is under investigation by this bureau at the present time, and we hope soon to know at least the fundamental facts."

### THE ROSENBACH AND AARON SIGNS

*To the Editor:*—Please describe (1) the Rosenbach sign and (2) the Aaron sign for appendicitis.

E. C. Brush, M.D., Zanesville, Ohio.

Answer.—1. We have been able to find three different signs known as the Rosenbach sign: (*a*) tremor of the upper lids in exophthalmic goiter when the eyes are gently closed; (*b*) loss of the abdominal reflex in cases of inflammation of the intestine, and (*c*) inability of neurasthenics to close the eyes immediately and completely on command.

2. We do not know what the Aaron sign is.

# Miscellany

## Medical Examinations After the French Revolution

On Aug. 18, 1792, the Constitutional Assembly of France passed a decree abolishing the medical faculties and societies and throwing open medical practice to any one who could pay for the privilege, the competitive examinations (*concours*) being mere farces. A chaotic state of affairs ensued, and had it not been for the law of 1794, establishing medical schools at Paris, Montpellier and Strasburg, to keep up the supply of army surgeons, France might in time have been under the absolute sway of quackery. On March 10, 1803, Napoleon, then first consul, put a stop to all this by a law which remained in force until Nov. 30, 1892, definitely establishing the status of physicians, surgeons, public health officers and irregular practitioners and requiring public examination of those seeking the right to practice. Dr. Ernest Wickersheimer, the scholarly librarian of the Académie de médecine (Paris), has just published an amusing protocol (*Paris médical*, 1913, x, 749) of an actual examination, held in 1804 in the department of l'Eure, by a jury presided over by Pierre Lassus of the Paris Faculté, which runs as follows:

First examination of Langlet, called La Chapelle, a self-styled "patented officer of health," in the presence of M. Lassus and the other members of the medical jury of l'Eure on the 8th Messidor of the year 12. Certain coarse and indecent remarks which he had made prior to his examination induced a member of the jury to attack him with the following questions:

Q. What is the clitoris?
A. The clitoris is the vagina, three parts together.
Q. Show us your stomach and your chest.
A. He showed one for the other.
Q. What is the eye?
A. The globe of the eye is composed of light; there is also extravasated blood and similar material.
Q. What is the ear?
A. The ear is the light which makes us understand things by its clearness, etc.
Q. How does a child come into the world?
A. A child comes as Adam, on its mouth, laboring the earth.
Q. What do you do when the anus is a blind alley?
A. If the man is dead, there is nothing more to do, still you might blow into the orifice to drive out the excrement by the mouth.
Q. What difference is there between a man and a woman?
A. The man has a virile member; the woman has two holes, the anus and the vagina.
Q. Where is the *fraise?*
A. In the umbilical bowel.
Q. Where is the pericranium?
A. In the placenta.
Q. Where is the atlas?
A. Among the vertebrae, or the shoulder-blade, or the spinal cord.
Q. Where is the peritoneum?
A. In the chest.
Q. What are the lungs?
A. They are the air, the breath of life.
Q. Where is the scrotum?
A. Near the anus and the vagina.
Q. What is the acromial apophysis?
A. It is the dislocation of the femur, or the round bone, or the tibia, of the fibula which comes out by its neck, a whirl, a sprain of cartilage.
Q. What is the great trochanter?
A. It is in the patella, tibia and fibula.
Q. Where is the sternum?
A. The sternum is above, inferior and within.
Q. Where are the atrabiliar capsules?
A. They are exterior.
Q. Where are the kidneys?
A. They are surcingular, exterior or above the girdle.
Q. Where are the suprarenal capsules?
A. Upon the kidneys.
Q. Where is the spleen?
A. Between the lungs and the livers, in the chest, where the livers have several branches.

Dr. Robert Fleig Library,
S. M. S. Medical College
22497

Q. Where is the thymus?

A. I am not a physician.

Q. Where are the cuneiform bones?

A. I give it up.

Q. Where is the pelvis?

A. The pelvis is the woman's region and nature.

Q. What is labor (*accouchement*)?

A. When the accouchement is for the time liquid and dilated, the fisobis presenting itself in the placenta, when the woman is in childbirth, her husband is scared to death and the woman about to be delivered has to remain in bed for six weeks, say the authors.

Q. After that what happens?

A. The clitoris being swollen with chagrin, prevents the woman from being delivered, the woman not proceeding in her trouble and the child not laboring for itself, cannot come into the world until the end of six weeks, on account of chagrin.

Q. What do you notice at the moment of delivery?

A. At the moment when a woman is delivered, the fundament enlarges and, for proof, I have seen a child and the excrement together in my hand.

Q. What are the ovaries? Where are they placed?

A. I renounce.

Second examination of Langelet La Chapelle, in the presence of the prefect of the department of l'Eure, Evrux, the 9th Messidor of the year 12.

Q. What is anatomy?

A. It comprises all the things of the body.

Q. How is the skeleton divided?

A. It is divided by the skull, occipital and cubital.

Q. What is the shoulder?

A. The shoulder is composed of the shoulder-blade and clavicle, forearm, ulna and radius.

Q. What is the wrist?

A. It is composed of the neck of the membrane.

Q. Describe the lower extremities.

A. It is composed of the thigh, patella, tibia, fibula, tarsus and metatarsus.

Q. What are the vertebrae?

A. All the vertebrae are of use. They are the essentials of man and his force.

Q. What are the loins?

A. I do not remember.

Q. How many ribs are there?

A. There are ten.

Q. What do you call the anterior bone of the chest?

A. It is the os sacrum.

Q. What is the peritoneum?

A. I do not remember.

Q. What are the lungs?

A. The breath, in the belly.

Q. Where is the heart?

A. In the chest.

Q. Where is the liver?

A. As it is in pigs.

Q. How many intestines are there?

A. Two; the large and the small.

Q. What is the cesarean operation?

A. It was Caesar who came into the world that way.

Q. How have you performed it?

A. By puncture, the bistoury being underneath the last rib, by an opening of four inches. After the first cicatrix, I opened, I took the infant in its receptacle, I placed the receptacle on the thighs of the woman, I sewed it up and put it back into the abdomen and I sewed the first cicatrix with an ordinary needle and a simple thread. The child lived; the bowels which came out were put back into the belly. I did this operation because the woman was feeble and without hope, and no pulse to be felt. She recovered without fever, kept her diet for four or five days; I dressed her with sugared wine. Six weeks afterward the woman was dancing in the assembly. The swelling had suppurated; I treated it with camphorated brandy; the swelling or thrombus still remains. This woman had a natural delivery one year before; a year afterward she was delivered very happily at the foot of a tree.

Q. How do you recognize a dislocation?

A. By the moving joints.

Q. How is a dislocated arm reduced?

A. I reduce it alone. I lift the arm and I reduce it with the finger in its proper place.

Q. What is the descent?

A. In the testicles, in the ring of the isles.

Q. What is the scrotum?

A. It is a part of women. It is placed at the fundament or anus. It is not an opening, it is a round part; it contains the vagina; it serves them for sitting down.

Q. Where is the spleen?

A. Above the womb.

Q. Where is the cerebellum?

A. In the head, in front.

Q. Describe the ear.

A. The ear is composed of temporals, occiput and parietals.

Q. Where are the seminal vesicles?

A. In the virile member, the bladder. In women, it is higher than in men.

The examiners in this droll questionnaire clearly understood their business. As it was plain that the candidate did not even know the parts of his own body, we can hardly blame them for exposing the extent of his ignorance by asking him about parts which do not exist. Dr. Wickersheimer does not state whether or not the candidate was successful, but the result may be inferred.

---

## Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF POSTGRADUATE WORK, CONTRACT PRACTICE, LEGISLATION, MEDICAL DEFENSE, AND OTHER MEDICOLEGAL AND ECONOMIC QUESTIONS OF INTEREST TO PHYSICIANS

### PRESENT ACTIVITIES IN PUBLIC HEALTH

The growing interest in public health is illustrated by the attention paid to this question by life-insurance companies and other business organizations, and the establishment of departments of public health by some of the state universities. Many of the insurance companies, large industrial concerns and special societies also issue pamphlets on various specific topics.

#### REGISTRATION OF VITAL PHENOMENA

Probably the most intimate connection between public health and business so far established is that between life insurance and vital statistics. Mr. Louis I. Dublin, statistician for the Metropolitan Life Insurance Company, recently delivered an address before the annual conference of health officers of Indiana, which has been reprinted in pamphlet form. After discussing the value of birth and death registration from a public point of view, Mr. Dublin takes up their value from a personal and commercial point of view, showing by cases from the records of life-insurance companies the importance and value of birth, death and marriage registration, and the commercial value of properly kept records. He concludes his paper by saying, "I hope that I have indicated the extent and character of the losses which result from neglect of thoroughly registering vital phenomena. If communities were to realize that they are called on ultimately to meet these losses, I think that we would have an awakening of public interest in careful civic accounting of human life. . . . . In life-insurance companies alone, fully one-fourth of the disputes would never arise were adequate records on hand. The saving of losses due to present litigation could then be returned as larger benefits to our clients, and would remove many causes for dissatisfaction. We cannot regard these losses as anything more than downright waste."

#### MISSOURI DEPARTMENT OF PREVENTIVE MEDICINE

The University of Missouri, like the University of Wisconsin, has established a department of public health. In Missouri it is known as the Department of Preventive Medicine. This department offers to furnish to any citizen of Missouri, on request, practical information regarding the prevention of disease. A laboratory is also equipped to make any necessary examinations, these services being free of charge to the people of the state. Three pamphlets have been issued so far, one on "Bacteria and Disease," by Dr. O. W. H. Mitchell, assistant professor of pathology and bacteriology; and pamphlets on "Typhoid Fever" and "Contagious Diseases Among Schoolchildren," by Dr. W. J. Calvert, professor of preventive medicine. The last-named pamphlet has just been issued. It contains three chapters, one on "The Nature of Communicable Diseases, and the Ways in Which They Are Spread," one on "The Symptoms of the More Common Infectious Diseases," and one on "School Hygiene," under the head of "Cleanliness, Pure Water, Ventilation and Heating." The recognition of public health as a legitimate field for the state university, and the establishment of a department of preventive medicine with a laboratory free to the citizens of the state, is a marked step forward in the social program for the prevention of disease. The recognition of the closely allied facts that prevention of disease is a social problem, and that it can be solved only through public education, is most important. In these two suggestions lies the solution of the problem of preventable disease.

### PURIFICATION OF WATER-SUPPLIES

The United States Geological Survey has issued "Water-Supply Paper 315," which is published as H. R. Document 1236, entitled "The Purification of Public Water-Supplies." In it are discussed the sources of water-supply for cities in the United States. In the northern and middle Atlantic states the use of lake and spring water is common. In the more southerly states waters from rivers are more commonly used, especially in the Mississippi and Ohio valleys. In nearly 400 cities, 40 per cent. of the water-supply is drawn from wells, 25 per cent. from lakes, ponds or springs, 24 per cent. from rivers, and 11 per cent. from mountain streams. The various sources of city water-supply are discussed, and the development of water-works systems in the United States, water consumption, typhoid fever in the United States and water purification, with an exhaustive discussion of methods and comparative values.

The section on typhoid fever shows that in 1900 there were over 35,000 deaths from this disease, and that in 1910 the typhoid fever death-rate in the forty-eight cities having a population of 100,000 or over was 23.3 per hundred thousand. Under the main subject of "Water Purification" the methods of slow and rapid sand filtration and the different means of sterilization are discussed, with illustrations showing water-purification plants in different cities.

### ARMY HOSPITAL REPORT

The medical department of the United States Army maintains a general hospital at Ft. Bayard, N. Mex. The report of this hospital. just issued, shows that 928 patients were treated there during the past year; 56 deaths occurred, 46 of which were from tuberculosis; 686 patients were admitted during the year, of whom 154 were returned to duty; of 672 cases of pulmonary tuberculosis 46 were incipient, 288 were moderately advanced, 337 were far advanced, and one was a case of acute miliary tuberculosis. Of these, 32 patients were apparently cured, 77 were arrested, 352 were improved, 160 were unimproved and 51 died.

## PAMPHLETS ON PUBLIC HEALTH AND ALLIED TOPICS

The most interesting literature on public health questions is to be found at present in pamphlets and bulletins rather than in books or journals. Most of the state boards of health publish pamphlets on various subjects for popular distribution. The variety of subject, method of treatment and material found in these pamphlets constitutes one of their most interesting features.

### NORTH CAROLINA HEALTH BULLETIN

The *Health Bulletin of the North Carolina State Board of Health* for October shows on the first page photographs of eight babies which have taken prizes at baby contests in various Southern states, and the announcement. "Watch this page for North Carolina prize-winners after the state fair." The cover also contains a list of pamphlets and leaflets printed by the state board for free distribution. This list includes such subjects as care and feeding of the babies, flies and mosquitoes, hookworm, malaria, tuberculosis and vital statistics. An article from the *Progressive Farmer*, "Why I am Down on Patent Medicines," gives practical advice to the reader on this subject. The writer says, "I recognize their (patent medicines) harm as any one may do if she cares to read the literature published by the United States government and the American Medical Association." A pertinent article on freight-rates, a subject which no one would suspect had a very intimate connection with health matters, shows that 16,000 of the 40,000 deaths in North Carolina last year were preventable, and that the 16,000 preventable deaths involved a loss of over $27,000,000 to the state; that of the 80,000 cases of illness in North Carolina last year 40,000 were preventable, and that this involved an additional loss of $18,000,000, or a total loss of $45,000,000, as the preventable health waste of the state for last year. The writer then continues, "When it is estimated that our state loses as much as $5,000,000 annually in excessive freight-rates we hold conventions and conferences, and we organize and call extra sessions of the legislature; but when we lose $45,000.000 worth of our best North Carolina citizenship no one gets excited, no one talks of an extra session. Why?" The writer then shows that the principal trouble is that the people do not realize the amount of the loss through preventable diseases and the fact that this is preventable. He assumes correctly that when these two facts are recognized by the people, "we will begin public health work in earnest. As it is now, there is practically no public health work done in over 85 per cent. of the counties in the state."

### VERMONT BULLETIN

The *Bulletin of the Vermont State Board of Health* for September contains the proceedings of the fifteenth annual school of instructions for health officers, which has been recognized as a state institution for a number of years, the state paying the expenses of all health officers attending. Different topics were presented by officers of the United States Public Health Service and of the State Department of Health, followed by discussion of the duties of local health officers. Two hundred and thirteen health officers were present.

### MICHIGAN PUBLIC HEALTH BULLETIN

*Public Health*, the bulletin of the Michigan State Board of Health, for September is devoted largely to articles on school hygiene. Charles F. Tambling of the Central State Normal School discusses "The Normal School in Sanitary and Civic Education." Charles McKinney of the Michigan State Normal School writes on "Sex Hygiene in the Public Schools." After discussing the question in general terms he summarizes the difficulties under four heads, namely, the opposition of present public opinion, the lack of teachers capable of giving suitable instruction at present, the lack of a well-thought-out and thoroughly tested course of study, and the objection to the teaching of sex hygiene in the elementary schools under present conditions. The first and the fourth objections are not especially weighty. The second and third, however, are deserving of the most careful consideration. The value or harmfulness of a course of instruction in sex hygiene or in any other subject in the public schools depends entirely on the carefulness with which a proper course of instruction is planned and on the ability and knowledge of the teachers who will have charge of the course. Even the most ardent advocates of teaching sex hygiene in the public schools must admit that as yet no carefully thought-out course of instruction, suitable for intermediate, primary and high schools has been prepared, and that in many cases the teachers are nearly as ignorant on this subject as are the pupils. McKinney says that until recently no special courses in sex physiology and hygiene were offered in any of the colleges or normal schools of the country; that only one normal college so far offers a course which would probably fit a person to teach this subject; that the literature on the subject, aside from controversal and propaganda pamphlets, is scarce, and that even what there is is of doubtful scientific value and decidedly emotional. McKinney strongly advocates the instruction of sex physiology in the public schools as soon as the right conditions can be secured, and outlines the following steps as necessary for this result: Continued agitation and enlightenment of the public regarding the social evil, the inauguration of proper courses in colleges and normal schools for the training of teachers in sex hygiene, the initiation of such courses in high schools before separate classes as a part of the course in physiology or physical training, and the extension of such instruction in the grammar and intermediate grades as fast as the courses and the teachers can be prepared for suitable instruction. McKinney's article is a thoughtful and conservative expression of opinion from one qualified to speak with authority. Other articles on "Rural School Hygiene," "Medical Inspection of Schools," "Schoolroom Cleanliness" and "School Water-Supply," make the number a particularly interesting one.

## A CITY'S INVESTIGATION OF ITS PUBLIC HEALTH

The present interest in social and civic conditions in American cities is no longer confined to the larger cities, but is being taken up in smaller towns. The citizens of Newburgh, N. Y., wanted to learn the facts regarding their city and its administration. First proposed by a local minister and later by the local Associated Charities, a survey committee of fifty citizens was ultimately organized which asked the cooperation of the department of surveys and exhibits of the Russell Sage Foundation. With the cooperation of a number of public workers, investigations were undertaken in the public schools on public health, housing, delinquency, public library, recreation, industrial conditions and municipal administration, the survey being in each case carried on under the supervision of an expert in each branch.

The investigation in the public health situation in Newburgh shows the weakness of much of our municipal health organization. The report criticizes the organization of the health department, which consists of a board of seven members, with the health officer as the executive and servant of the board, instead of an expert administrator responsible for the work of the department. Another serious difficulty is the fact that the health officer is expected to give only an hour a day to the work of the department. One is not surprised at this situation when it is learned that Newburgh spends only 12 cents per capita per year for health purposes, or about 1 cent a month or a quarter of a cent a week to guard the health of each citizen. Certainly not much can be expected for this sum. The registration of births and deaths and the reporting of diseases is also criticized, more on account of the defects in the system than on account of personal shortcomings. Newburgh, it seems, is known as a "typhoid town," and the survey finds ample evidence to justify this designation. In the opinion of the inspector the presence of typhoid is entirely inexcusable and represents an economic loss to the city of about $40,000,000 a year. While the sewer system of the city is good, no one seems to know anything about the condition of the milk-supply, with the result that one infant out of every eight dies during the first year of life.

Tuberculosis, venereal diseases, medical inspection of schools, the lack of suitable hospitals, hospital equipment, street-cleaning, occupational diseases and other important subjects are also gone into in the report. The recommendation made is for a full-time health officer with a suitable salary and with proper authority and responsibility, with such assistance as he may need to organize and operate a modern municipal department of health. The report is summarized so that the issue is put plainly before the citizens of Newburgh, that the securing of a proper department of health and the prevention of diseases and the saving of life is simply a question of finance. The report on housing is also of interest from the public health point of view, covering lodging-houses, sewer connections, danger from fires, etc. The entire report is of interest as an example of the careful scrutiny to which all fields of municipal activity are now being subjected.

# *Medical Education and State Boards of Registration*

## COMING EXAMINATIONS

ARIZONA: Phoenix, January 3. Sec., Dr. John Wix Thomas, 200 National Bank of Arizona Bldg., Phoenix.

COLORADO: State Capitol, Denver, January 6. Sec., Dr. David A. Strickler, 612 Empire Bldg., Denver.

DELAWARE: State Society and Homeopathic, Dover and Wilmington, Dec. 9-11. Secretary of the Medical Council, Dr. Henry W. Briggs, 1026 Jackson St., Wilmington.

IOWA: The Capitol Bldg., Des Moines, January 6-8. Sec., Dr. Guilford H. Sumner, Capitol Bldg., Des Moines.

KENTUCKY: Armory, Louisville, Dec. 11-13. Sec., Dr. J. N. McCormack, Bowling Green.

MARYLAND: Regular, 1211 Cathedral St., Baltimore, Dec. 9. Sec., Dr. J. McP. Scott, Hagerstown.

MINNESOTA: State University, Minneapolis, January 6-9. Sec., Dr. Thos. S. McDavitt, 814 Lowry Bldg., St. Paul.

NEW HAMPSHIRE: State House, Concord, January 6-7. Regent, Mr. H. C. Morrison, State House, Concord.

NORTH DAKOTA: Grand Forks, January 6. Sec., Dr. G. M. Williamson, Grand Forks.

OHIO: Columbus, Dec. 9-11. Sec., Dr. Geo. H. Matson, State House.

OREGON: Portland, January 6-8. Sec., Dr. L. H. Hamilton, Medical Bldg., Portland.

PENNSYLVANIA: Philadelphia, Dec. 2-4. Sec., Mr. Nathan C. Schaeffer, Harrisburg.

VIRGINIA: Richmond, Dec. 16-19. Sec., Dr. Herbert Old, Norfolk.

WASHINGTON: Spokane, January 6-12. Sec., Dr. F. P. Witter, Traders' Block, Spokane.

### Correction of West Virginia July Examination Report

In the report of the examination held by the West Virginia Board in July, 1913, one candidate was reported as a graduate of the University of Louisville. A foot-note stated that information from the college did not indicate such graduation. A later report from the West Virginia Board states that the candidate should have been given as a graduate of the Chicago College of Medicine and Surgery.

### Vermont July Report

Dr. W. Scott Nay, secretary of the Vermont State Board of Medical Examiners, reports the written examination held at Burlington, July 8-10, 1913. The number of subjects examined in was 12; total number of questions asked, 90; percentage required to pass, 75. The total number of candidates examined was 23, all of whom passed. One candidate was licensed through reciprocity. The following colleges were represented:

PASSED

| College | Year Grad. | Per Cent. |
|---|---|---|
| Tufts College Medical School | (1909) | 85.9 |
| Albany Medical College | (1911) | 81.7 |
| Columbia Univ., Coll. of Phys. and Surgs., N. Y. | (1913) | 91.4 |
| University of Vermont (1911) 77.2; (1912) 80, 92.8; (1913) 77.5, 78.1, 79.5, 79.8, 80.1, 81, 81.7, 81.9, 82.1, 83.5, 84.9, 85, 85.6, 86.1, 88.1, 92.7. | | |
| University of Naples | (1904) | 80.2 |

LICENSED THROUGH RECIPROCITY

| College | Year. Grad. | Reciprocity with |
|---|---|---|
| Baltimore Medical College | (1896) | Maine |

### Missouri June Report

Dr. J. A. B. Adcock, secretary of the Missouri State Board of Health, reports the written and oral examination held at St. Louis, June 16-18, 1913. The number of subjects examined in was 14; total number of questions asked, 210; percentage required to pass, 75. The total number of candidates examined was 160, of whom 144 passed and 16 failed. The following colleges were represented:

PASSED

| College | Year Grad. | Per Cent |
|---|---|---|
| | (1911) | 80.8 |
| Howard University, D. C. | (1913) | 87.1, 88.1 |
| University of Illinois | (1912) | 86.1, 89.6 |
| Rush Medical College | (1912) | 88.3 |
| Chicago College of Med. & Surg. (1913) 87.2 | (1913) | 85.6 |
| Hering Medical College | (1913) | 87.2 |
| Drake University | (1913) | 86.2, 88.2 |
| Tulane University, New Orleans | (1913) | 87.3 |
| Johns Hopkins University | | |

# Book Notices

MASSAGE. Its Principles and Technic. By Max Böhm, M.D., Edited, with an Introduction, by Charles F. Painter, M.D., Professor of Orthopedic Surgery at Tufts College Medical School, Boston. Cloth. Price, $1.75. Pp. 91, with 97 illustrations. Philadelphia: W. B. Saunders Company, 1913.

Considering the fact that literature on the technic of massage, particularly in English, is very rare one will acknowledge that the author is filling a want. The book is short, to the point and ought to be well received. There is first a chapter concerning general preparations and length of sitting, as well as definitions of the various manipulations; then well-illustrated chapters on the massage of joints, muscles, nerves and skin, abdomen and the general body massage. There are also a few anatomic pictures illustrating why it should be done just so. One might, of course, find reasons for difference of opinion. On page 38 there is a description and illustration (Fig. 21) of the way in which by raising the arm, one can get at the capsule of the shoulder-joint and manipulate it, in case it is thickened. Of late, writers on massage advise against vigorous manipulation in the axilla, as one might harm the brachial plexus, and we are inclined to endorse that opinion.

ANAPHYLAXIS. By Charles Richet, Professor in the Faculty of Medicine, Paris. Authorized Translation by J. Murray Bligh, M.D., Medical Registrar to the Liverpool Royal Infirmary with a Preface by T. R. Bradshaw, B.A., M.D., F.R.C.P. Cloth. Price 3 shillings 6 pence. London: Constable & Co., 1913.

To Richet belongs the credit of first giving to the profession a comprehensive account of the main phenomena designated by "anaphylaxis," the word coined by him to signify the opposite of protection or phylaxis. Because there appeared to develop an increased sensitiveness to a poison after previous injection of that poison this new word seemed quite appropriate. We now know, paradoxical as it may seem, especially in the light of the symptoms, that there is no actual increase in susceptibility to poisons in anaphylaxis, but an increase in the power of the body of the so-called sensitive animal to split the sensitizing protein into poisons. Failure to distinguish clearly between the original meaning of anaphylaxis and the real nature of the condition to which it is now applied is a serious obstacle to a clear understanding of what is written and said about this subject. This distinction must be kept in mind constantly in reading Richet's account of the various phases of anaphylaxis, or perhaps better allergy. All students of allergy will welcome this presentation of the subject by one who has contributed so much to our knowledge of it. Generally speaking, his views accord with those current in American and German literature. Only little effort is required to accommodate one's self to Richet's nomenclature. In places the statements are abrupt and even obscure, perhaps because of the translation; but examples of the masterly lucidity of the French are not wanting. The physician who is not already thoroughly familiar with the general facts in regard to anaphylaxis will find this a rather difficult book to understand, as the author frequently appears to assume a considerable knowledge on the part of the reader. It is annoying that there is no index and it is difficult to see why the bibliography in the English edition should have been limited to the years 1910, 1911 and part of 1912.

DIGEST OF COMMENTS ON THE PHARMACOPEIA OF THE UNITED STATES OF AMERICA (EIGHTH DECENNIAL REVISION) AND ON THE NATIONAL FORMULARY (THIRD EDITION). For the Year Ending December, 1911. By Murray Galt Motter and Martin I. Wilbert. Paper. Pp. 683. Hygienic Laboratory, Bulletin No. 87. Washington: Government Printing Office, 1913.

In the period covered by this, the seventh in the series of "Digests," the critical character of the comments on the German Pharmacopeia might be taken to indicate that the makers of pharmacopeias must in the future cater to a more and more discriminating constituency. This attitude on the part of users of pharmacopeias is still further emphasized by the growing demand for a limited materia medica and, by inference, the limitation of the scope of the pharmacopeia to substances of recognized therapeutic efficacy and substances which, to some degree at least, lend themselves to adequate standardization, whether chemical or physiologic. Coupled with this is the demand, now become international, for greater uniformity in the matter of nomenclature and of standards, together with the tests for purity and identity, and the method of making these tests, on which the standards are based. These tendencies are well reflected in this volume, nearly two-thirds of which is devoted to comments on official articles. The twenty pages or more devoted to the subject of clinical tests should prove a real aid to those physicians and pharmacists who have the time, the inclination and the facilities for clinical laboratory work, while a score of refences to the literature on disinfectants presage the coming of light and order in the somewhat chaotic field of modern preventive medicine.

BEHANDLUNG DER ANGEBORENEN UND ERWORBENEN GEHIRNKRANKHEITEN MIT HILFE DES BALKENSTICHES. Von Prof. Dr. G. Anton, Direktor der königl. Klinik für Geistes- und Nervenkrankheiten in Halle, a.S., und Prof. F. G. von Bramann, Direktor der königl. Chirurg. Universitätsklinik in Halle a.S. Paper. Price, 9 marks. Pp. 188, with 54 illustrations. Berlin: S. Karger, 1913.

In this monograph are described the underlying principles, the technic and the results, in a variety of cases, of efforts to relieve intracranial pressure by puncture of the corpus callosum. The clinical histories of the cases in which the procedure has been used, which represent hydrocephalus, hypophyseal tumors, tumors of the brain and cysticercus, are given in full. On the basis of the experience here recorded the indications, contra-indications and possible dangers of the operation are discussed. It appears that in inoperable intracranial tumor the pain and the distress of the patient may be greatly relieved by puncture of the callosum, and that good results have been obtained in other cases of intracranial pressure. The monograph consequently is of interest and importance to surgeons.

PROTECTIVE INOCULATION AGAINST CHOLERA. By W. M. Haffkine, Bacteriologist with the Government of India. Paper. Price, 4 shillings 6 pence net. Pp. 98. Calcutta: Thacker, Spink & Co., 1913.

The author gives an account of his work in the preparation of an anticholera vaccine and of its application to the prevention of cholera in India. This occupies the first two parts of the book. The third deals with the effects of devitalized "Cholera Vaccine II," as he calls his preparation of living cholera germs. He regards it as demonstrated that dead cholera germs will produce immune bodies in the human organism; but experience must show whether or not the preparation will protect man against cholera germs taken into the intestinal tract. Experiments to test this point should soon be made, since the greater convenience of the devitalized vaccine will render it much more useful than the living germs in immunizing large numbers of people.

WHAT HEART PATIENTS SHOULD KNOW AND DO. Suggestions for Persons Suffering from Diseases of the Heart and Blood-Vessels. Exercise, Diet, Prevention, etc., and Advice as to the Regulation of Their Lives. By James Henry Homan, M.D., Special Lecturer on Cardiovascular Diseases in the University of Georgia. Cloth. Price, $1.20 net. Pp. 204. New York: Dodd, Mead & Co., 1913.

The author has written a book of advice ostensibly for patients suffering from heart-disease, but its scope is so diffuse that it can be regarded as advice applicable to any one quite as much as to the sufferer from heart-disease. The book is best described by the following headings: "Relaxation," "Clothing," "Climate and Environment," "Exercise," "Diet," "Bodily Waste," Blood-Pressure," "Obesity," and the advice given by the author is conservative and good. It is not better than many books already on the market giving general hygienic advice, and the literary style is not so good as some of the others.

GRUNDRISS DER FERMENTMETHODEN. Ein Lehrbuch für Mediziner, Chemiker und Botaniker. Von Professor Dr. Julius Wohlgemuth, Assistent am Kgl. Pathologischen Institut der Universität Berlin. Paper. Price 10 marks. Pp. 355. Berlin: Julius Springer, 1913.

The purpose of this book is to describe clearly all the methods that have proved useful in the study of ferments. The intention of the author has been to meet the needs of the practical laboratory worker, and the directions are given with much care and detail with the view of helping those who are less experienced. In the general part the nature of ferments and the fundamental principles of their study are discussed in a clear and simple way; in the special part, the methods for the different classes of ferments are given. In view of the growing importance of the study of ferments in diagnosis, the book will interest all physicians who are in touch with the development of recent work.

## Breach of Contract to Furnish Employee Medical Attention

*(Thomas vs. Tennessee Coal, Iron & Railroad Co. (Ala.), 69 So. R. 627)*

The Supreme Court of Alabama reverses a judgment rendered in favor of the defendant, which was sued for damages for failure to furnish the plaintiff necessary medical attention when he became ill with severe cramps and pain in the abdomen, while in the defendant's employ. According to the plaintiff's testimony, which did not seem to be in any way contradicted, the defendant's agent assured him, when he entered the defendant's service, that for the payment of $1 a month, "in case that you or any of your family gets sick, why, the company doctors will give you service." It was not disputed that the defendant had in its employ at that time, and at the time that the plaintiff became ill and required medical service, a practicing physician charged with the duty of giving needed medical service to its employees at its plant at which the plaintiff was employed. The physician's contract with the defendant, however, was to serve employees and their families at their homes within a restricted territory only, whereas the plaintiff's residence, where he was taken sick, and where the physician was called on to visit him, lay a mile or more outside of that territory. Still it did not appear that the plaintiff was informed of this restriction, and it was not denied that the defendant deducted the stipulated fee of $1 a month from the plaintiff's wages as consideration for the medical service promised to him and his family.

It resulted, the court says, that, while the physician was not obligated to either the plaintiff or the defendant to render the service requested in this particular case, the defendant was none the less obligated to the plaintiff to have the physician do so; at least the contract between them was fairly open to that interpretation by the jury, and fairly open to the interpretation, also, that in case of need the company's physician should be summoned by a call made immediately on him, and not mediately through some other company official. For if the company's physician, provided for such an emergency as here arose, failed or refused to respond to the plaintiff's call, the plaintiff was certainly under no duty to wait and take the matter up with the company for negotiation and adjustment, and, perhaps, die the meanwhile of inattention and neglect, as it seems he would very likely have done.

So far as the defendant's obligation to the plaintiff was concerned, the limited service it required of its regular physician, the fact that that physician was under no duty to travel outside of a designated territory to serve the plaintiff at his need, was wholly immaterial to the case, in the absence of notice to the plaintiff of such a restriction when he was contracting and paying for a service not thus limited. It might, indeed, be reasonably presumed that for mere service at the plant or infirmary in case of injury he would not have chosen to pay the monthly fee; and, without informing the plaintiff of the stated restriction, the defendant had no right to take his money, and at the same time fail to provide for needed medical service to him at the hands of its regular physician.

This was the breach averred in one count of the complaint, and there was evidence before the jury to support it. The breach charged was a breach by the defendant, not by the physician, and the physician's refusal to attend the plaintiff was, in law, a failure by the defendant to discharge its duty to the plaintiff, namely, to arrange with its regular physician to attend him in sickness, and to actually effect such attendance by that antecedent provision. The trial court erred, therefore, in instructing the jury to find for the defendant, and its judgment must be reversed.

## Construction and Validity of Law Prohibiting Obnoxious Disease and Deformity Exhibitions

*(People vs. Kennedy et al. (Mich.), 141 N. W. R. 887)*

The Supreme Court of Michigan affirms a conviction of the defendants under the Michigan statute entitled "An act to prohibit, discourage and punish the exhibition of deformed human beings, diseased or deformed human bodies, or parts thereof, or the representations of the same, for any other than purely medical purposes." The prosecution was under Section 2, which provides. "It shall be unlawful for any person or persons to so expose or exhibit in museums or elsewhere diseased or deformed human bodies, or parts thereof, or representations of the same, which would be indecent in the case of a living person, except as used for scientific purposes before members of the medical profession or medical classes."

It appeared that the defendants were engaged in the practice of medicine in the city of Detroit and occupied the three upper floors of a building. At the entrance to their offices was a sign reading, "Doctors K. & K. Museum." On the upper or fourth floor, contained in cases, were representations, in wax or other substance, of portions of human bodies of both sexes described within the prohibition of the statute. The complaining witness, on application, went up in company with the defendants' office boy, who, under the direction of the defendants, occasionally took people up to the fourth floor, opened the door for them, and turned on the light. Those taken up by him were always adults and only one at a time. The defendants contended that for years this collection had been stored in the attic of another building not accessible to anybody; that, after they occupied their present location, they moved it from the attic, had the different pieces painted and mounted, and placed them on this top floor "so that they could be seen favorably, in case we wanted to sell them"; that they tried at different times to make a sale; that they were not exhibited to the public. One of them testified. "We do not exhibit this stuff to the public. Once in a while if a person calls, we send them up. Sometimes we refuse people."

It was argued that Section 2 is unconstitutional because not within the scope of the title of the act, and because the offense charged in that section is not embodied in the enacting clause. But, the court says, as appears from the entitling of this act, it is a police regulation clearly within the power of the legislature, and was enacted to prohibit, discourage and punish the exhibitions therein described. The objection was without merit for the reason that the exhibition of the representations of the parts of the human body prohibited by Section 2 of the statute charged and described in the complaint was clearly within the terms of the entitling of the act. The exhibition prohibited by this section of the statute might be either public or private and includes an exposure to a single individual.

The construction of this portion of the statute is one of first intention before this court, and it will be proper to say that the defendants' contention was that the legislative intent in this statute was to prohibit the exhibition in public of the prohibited subjects, with or without charge, and that the words "exhibition," "expose," and "exhibit" should be construed in harmony with such intent, and the jury should have been so instructed. But the court does not think that Section 2 should be so construed. The legislature intended by this section to prohibit the exposure of these subjects in public or in private to any person or persons, "except as used for scientific purposes before members of the medical profession or medical classes." In the court's opinion it is a statute enacted in the interest of morality and decency. The terms of the statute are not technical, and the words used should be given their ordinary and usual meaning.

## CHICAGO MEDICAL SOCIETY

*Regular Meeting, held Nov. 12, 1913*

The President, Dr. Charles P. Caldwell, in the Chair

### Relations of, and the Lesions Produced by, Various Forms of Streptococci, with Special Reference to Arthritis

Dr. E. C. Rosenow: About a year ago I became interested in the question of the transmutation of the pneumococci and streptococci, or the various organisms of the streptococcus group. It had been known previously that certain streptococci may take on cultural features and other properties quite different from those they had when first isolated. Indeed, the form of endocarditis which we have known clinically as chronic septic endocarditis is caused by a streptococcus, the so-called *Streptococcus viridans*, which by animal passage can regularly be converted into pneumococci. It is generally considered that the *Streptococcus viridans* is an intermediate organism between pneumococci, on the one hand, and streptococci on the other. I felt that it might be possible for a typical pneumococcus, for instance, to be converted into a typical streptococcus, and this has been done. The transformation is so complete that I have no hesitation in saying that if a bacteriologist can differentiate a typical pneumococcus from a typical streptococcus, then it is possible to transform one into the other, and as we transform pneumococci into streptococci there are intermediate states and intermediate organisms. At a certain stage in the transformation of one organism into another — the hemolytic streptococcus, for instance, into the *Streptococcus viridans* — it behaves culturally and looks like the *Streptococcus viridans*, when injected into rabbits it will produce the lesions more or less characteristic of that organism, producing a typical endocarditis, and that of a type similar to the one produced by the organism as isolated in the case of the chronic septic endocarditis. When you increase the virulence of this organism somewhat, it will take on cultural and other features resembling the organism isolated from cases of rheumatism, and as you increase its virulence still further it will take on the characteristics of a pneumococcus.

We know that hemolytic streptococci have a marked affinity, experimentally, for the joints of animals, and we know, too, that it is likely that hemolytic streptococci have a marked affinity for the joints in man. A typical hemolytic streptococcus was isolated originally from a case of tonsillitis. That organism, when injected into animals, showed a marked affinity for the joints, producing an arthritis repeatedly. A blood-vessel had in it a clot containing rather a large number of streptococci. An animal was injected intravenously with another strain of hemolytic streptococci, and when it was killed five days later a multiple arthritis of the suppurating type was found. A section of the synovial membrane taken from the neighborhood of the plica showed a thrombosed vessel containing round cells, with streptococci in the blood-vessel as well as in the surrounding tissue.

In another experiment, the first strain of organism, a hemolytic streptococcus, was transformed into a *Streptococcus viridans*. Instead of having the single coccoid forms in the chain, there was a tendency to chain formation, and a marked tendency to form in clumps. This hemolytic streptococcus was converted into *Streptococcus viridans* in the test-tube by simply placing it in symbiosis with the *Bacillus subtilis*. When it acquired this morphology, it acquired, when injected into an animal, features and the affinity for the heart-valve instead of the joint, producing now the same organisms repeatedly, and hemorrhage in the heart-valve and endocarditis, without producing arthritis.

A man had had an attack of articular rheumatism. He suddenly began to have severe muscular pain all over the body, with distinct localizations in various muscles, the intercostal muscles especially, the flat muscles of the skull, the occipitofrontalis, and the muscles of the shoulders. He had a beautiful lesion in the supinator longus and also in the biceps, in each instance within the tendon sheath. A cross-section of the biceps muscle showed the striation of relatively normal muscle with round-cell infiltration and hemorrhage, and a nodule somewhat larger than we find in the animal, but very typical. That is not only evidence of a real myocarditis, represented here in a man, but from this area the same organism reproduced myocarditis in a rabbit, and the organism was again isolated from that rabbit.

This affinity for these various structures is not merely accidental; it is certain. When the rabbit has acquired that affinity it is so marked that you can inject half a dozen animals with varying doses of bacteria and have a number of lesions produced in proportion to the size of the injection. Moreover, you can inject that same strain of organism and pass it through one animal, and in the next passage it will probably produce a few muscle lesions, or none at all, and after the second and subsequent passages you can do what you will, but you cannot produce a muscular lesion. The facts are that at certain stages of morphology, chemistry, or what not, these affinities for localization are absolute and very distinct.

We have discussed the marked and really characteristic affinity of hemolytic streptococci for joints—the evidence in man. The evidence, experimentally, is complete. We have shown that the organisms isolated as *Streptococcus viridans* have a marked affinity for the heart-valves, producing clinically that form of endocarditis that is so fatal, the chronic septic endocarditis, and a fatal endocarditis in rabbits. We have shown that the *Streptococcus rheumaticus* has the same affinity, but in no instance producing the lesions so badly as in the others.

These organisms have an affinity for other structures of the body—the mucous membrane of the stomach of a dog, which shows a large area of necrosis forty-eight hours after an intravenous injection of streptococci; the mucous membrane of a rabbit's stomach showed a beginning ulceration forty-eight hours after injection.[1]

Experimentally, the ulcers which I have produced by the intravenous injection of these organisms resemble more the type of ulcer seen in man than has been noted by other observers. The possibility of ulcer of the stomach in man being infectious, and the evidence that ulceration in the duodenum or stomach may have its origin as an infection, surely is suggested by results of this kind. I have made cultures from ulcers in man, and in two of those ulcers I was able to isolate streptococci, not from the surface, but from the depths of the ulcer. In one of these the affinity for the mucous membrane of the stomach in dogs was more marked than any other, producing a most beautiful ulceration in the stomach, and a slight, low-grade enteritis, and that was all the dog had. In the animals in which these organisms produced ulceration of the stomach the most common associated lesion was a cholecystitis, and beginning gall-stone formation. When the organism of rheumatism is injected, it is common to obtain marked ulceration and inflammation of the appendix in addition to the joint lesion. The organism from articular rheumatism has never produced ulceration of the mucous membrane of the stomach until it has been passed through a number of animals.

Owing to the cooperation of Drs. Mayo, Bevan and Ochsner I have been able, in conjunction with Dr. Sanford, to study the bacterial flora of four chronic duodenal and gastric ulcers, together with the regional lymph-glands in one. The number of colonies of organisms were very few, staphylococci being the predominant organism. In two cases, however, we obtained streptococci and one of these showed an affinity for the stomach mucous membrane of rabbits and dogs which was very striking. These results are very suggestive of the work which may be accomplished if surgeons will cooperate to furnish clinical material for study of this nature.

The affinity for the stomach mucous membrane is great; the affinity for the mucous membrane of the gall-bladder is also great. The production of inflammation of the gall-bladder is not always, I am absolutely sure, an expression of the bile, secondarily infecting the gall-bladder, but it is an inflammatory process just as in the heart-valve and in the joint, proving absolutely that the mode of origin in some instances, in which the conditions were ripe, was embolic, and that the bile was infected secondarily from the nodular inflammation in the mucous membrane and the ulceration.

One of the lesions that is most common about this grade of virulence, although a little higher virulence is more favorable, is the picture of an ascending pyelonephritis. I shall never have any trouble in the future, after seeing the results of these experiments, in explaining where the infection comes from in a patient with gall-stones who has not the history of typhoid, and I shall no longer have any trouble in satisfying myself where the infection comes from that forms the nucleus of a mural renal stone. I feel that the question of ulcer of the stomach and duodenum is entirely within control by proper methods, and that surgeons must come to our aid.

### Clinical Aspects and Medical Management of Arthritis Deformans

Dr. Frank Billings: The beginning of this work on joints started with an investigation of chronic infectious endocarditis, when the *Streptococcus viridans* was discovered in the circulating blood of patients suffering from this disease; but with such a worker as Dr. Rosenow that organism soon was chased down to a pneumococcus, and the report which I made at Atlantic City about seven years ago followed. These cases were reported as pneumococcus endocarditis, which was disputed by Eastern men and others, who said that we had made a mistake; but subsequent reports and Dr. Rosenow's report to-night prove that the work done in those days by him, that of the transmutation of *Streptococcus viridans* into the pneumococcus, was correct. Following that came the work on the joints, and we have gained a knowledge of arthritis deformans that we have not had before.

Chronic arthritis with deformity is, in my opinion, primarily of infectious origin. Usually the infectious micro-organism is a streptococcus. The work of Rosenow shows that the cultural and pathologic characteristics of the streptococcus may be changed by varying the culture-medium and by serial animal inoculation. The occurrence of chronic infectious endocarditis due to the *Streptococcus viridans*, the acute arthritis rheumatica of chronic arthritis due to a streptococcus, of myocarditis, acute and chronic, due to still another strain of the streptococcus modified from strains of other streptococci by varying the culture methods, seems to show that the mutation of these strains may occur in the animal or man at the point of focal infection. It is an important principle, not yet absolutely proved, that an organism can be transformed in cultural characteristics and pathogenic quality in the test-tube and by passage through animals, and is suggestive that the same organism in man, focally situated, may change and produce various lesions, in one endocarditis, in another acute arthritis, in another myocarditis, with or without chronic arthritis of a deforming type.

Confusion has arisen from the attempt to classify deforming joint disease anatomically. In the same patient one may find varying anatomic changes, these depending on the source of the blood circulation of the joint, in part, and apparently, also, on the resistance of the tissues to the infectious agent, and, finally, to the degree of virulence of the micro-organism infecting the tissues of the joint. The circulation to the joint structures consists of three separate systems: that to the periarticular structures, that to the synovial membrane and its reduplication, and that to the medulla of the bone in the shaft. This explains the variety of anatomic changes which occur in any form of chronic arthritis. If you will examine these patients carefully, you will sometimes find all types in one individual, but not in all. Practically all patients with deforming arthritis suffer from chronic myocarditis with interstitial overgrowth, and consequently contraction. Heretofore this muscular contraction has been thought to be due to nervous influence, or a secondary event in chronic arthritis, due chiefly to the posture of the limbs involuntarily assumed to relieve the pain in the joints. This is true in some instances, or in part in all possibly, but in arthritis deformans the shortening occurs in muscles when near-by joints are not involved. Culture yields in many instances micro-organisms of a streptococcoid type. It is our opinion that these are the cause of myositis and will probably prove to be mutation forms of the streptococcus organism found in the tissues and nodes of arthritis deformans.

In addition to the primary infectious origin of the invasion of joints and muscles in arthritis deformans, there is unquestionably an associated, probably secondary, change in metabolism which intensifies the anatomic joint changes, and is further manifested by a general nervous irritability, frequently a secondary anemia, loss of weight, disturbed digestion, etc. In part, the poor general nutrition is due to the protracted illness, with deprivation of proteins, and lessening of the general strength by hot baths, and by too much irrational drugging. In addition, there are metabolic changes in bones, cartilage and ligaments, and in the muscle tendons, which we do not understand. The best example is the poker-spine of a spondylitis deformans, which has been compared with the melted tallow which flows down and hardens on the candle. Possibly, future study may explain this, and also that these metabolic processes are set up as a reaction to the bacterial toxins.

Therefore, I would consider arthritis deformans as a clinical entity based on the established proposition of the existence of a chronic focus of infection due to a streptococcus which is usually located in the faucial tonsil or in the antra of the head, or in the jaw, related to the alveolar processes, or more rarely the gall-bladder, appendix, prostate or elsewhere. The streptococcus is isolated from the infectious focus and is susceptible of mutation in cultural characteristics and pathologic effects. Finally, there is an associated chronic myocarditis, apparently due to a type of streptococcus that has no affinity for the muscles. I think that this clinical entity due to the streptococcus may be differentiated from other infections of chronic arthritis, if one keeps in mind the characteristics which I have mentioned.

---

[1] See article this issue, p. 1948.

Gonorrheal arthritis and especially spondylitis due to the gonococcus may be difficult to separate from arthritis deformans; but the gonococcal focus may be located in the urinary tract, the prostate or more frequently in the seminal vesicles, and thus settle the question. I have never seen the Neisserian organism cause a myositis.

The first step in the treatment is a thorough investigation of each patient. An attempt must be made to find the focal cause. While I believe that the faucial tonsil is more frequently the seat of focal infection than any other point in the body, still a thorough examination must be made of the sinuses, the teeth, the jaw and the pelvic organs as to the possible presence of a chronic focus of infection in the gall-bladder or appendix, and in the event of gastro-intestinal diseases, associated especially with stasis of the intestinal contents, a study of the feces as to the intestinal flora should be made. If the patient has suffered from frequent attacks of tonsillitis, if the tonsils show infected crypts, even though they be small, they should be removed. A large fibrous tonsil rarely causes the trouble. It is the small tonsil, usually, that contains the infectious organism in an obstructed crypt or an abscess cavity. My point is not to limit the investigation to the tonsil, but to search for the possible focus of infection elsewhere. If none is found elsewhere, it is my opinion that the tonsils should be removed, even though the history is negative to attacks of tonsil disease.

The aid of the orthopedic and general surgeon is frequently necessary to correct deformities due to contracted muscles, and in the application of proper temporary braces, etc. The surgeons have even restored dislocated joints for us and stretched the contracted muscles by putting on splints. The hygienic management does more than any other one thing to improve the patient.

Finally, immunity is still further established by the judicious use of autogenous vaccines, repeated every five or six days, in doses varying from 50 to 200 million. We used to employ larger doses, but experience showed quite as good results from the use of smaller doses without some of the disadvantages of excessively large doses. I have yet to see one patient who suffered from arthritis deformans improve under treatment with stock vaccines. This is probably due to the fact that the source of the infection has not been searched for and removed.

Arthritis deformans is an infectious entity. There is a varying degree of joint involvement, sometimes proliferative or hypertrophic, sometimes degenerative or atrophic. In practically all patients there is a chronic myositis, sometimes quite generalized. Practically always there is a general debility, a malnutrition, and probably a secondary faulty metabolism. The focal infection which may give rise to arthritis deformans is usually located in the head, but may be located elsewhere in the body.

The treatment and management must comprise: (1) the removal of the cause; (2) improvement of the general condition of the patient and resistance to the infectious organism by a personal hygiene, including good food, pure air, rational calisthenics and graduated exercises, with cheerful environment, and (3) the use of autogenous vaccines. The treatment of such cases should be carried on in a hospital in which team-work of the staff may be used for the investigation and removal of the cause, and subsequent treatment, both medical and surgical, may be carried out.

### Etiology of Biliary Tract Infections and Their Relations to Duodenal Ulcer and Appendicitis

DR. CHARLES L. MIX: The blood-supply of this region has something to do with the distribution of the lesions. The superior mesenteric artery is the supply of the appendix, and the region of the pylorus is supplied by the hepatic artery primarily, and that branch known as the superior pancreaticoduodenal. This one artery supplies both the gastric and the duodenal side of the pylorus. It supplies that part of the pylorus which hangs free in the gastrohepatic omentum, or, rather, fastened to it by the hepaticoduodenal ligament. This one artery supplies, therefore, that portion of the stomach which is the site of the ulcer, and it is not at all unlikely, in accordance with the embolic theory, that the emboli may enter on either side of the pyloric line, or in it. They may pass into the pyloric branch of the hepatic, but it is more likely, since the pathway of infection is more straight through the gastroduodenal, that they may pass straight down that pathway in somewhat the same manner as infection passes up, as a rule, to the left side of the brain from the arch of the aorta in cases of cerebral embolism.

The lymphatic supply of this region also merits attention. The appendix has coming from it two sets of lymph-vessels, or, one might say, three. There are in all of the mucous membrane structures two sets of main lymph-vessels. These have not been described until recently. One of these lymph-vessels, and a very important and somewhat disregarded one, is that which runs in the mucous membrane itself, and is so near the surface of the mucous membrane that it for a long time escaped attention. The next set is that which runs in the submucosa, and then outside of that, beneath the peritoneum, is another subserous set of lymph-vessels. These three sets are more or less distinct from one another. Coming from the appendix, therefore, is a set of currents which may ascend into the cecum, and then up the colon, in this mucous layer of lymph-vessels, or we may have the lymphatic current passing along the subserous surface, but along the colon, giving rise to certain cases of inflammation and extension of peritonitis, localized, sweeping up along the cecum toward the ascending colon, and producing numerous adhesions.

In the region of the duodenum, pylorus and stomach there is the same set of lymph-vessels. The mucous lymph-vessels are directly continuous through the pylorus, so that the gastric mucous lymph-vessels, the pyloric mucous lymph-vessels and the duodenal mucous lymph-vessels form one system. There is a similar system in the muscular and another in the subserous coats. These all make their way into nodes which pass up first along the gastroduodenal artery and then to the lymph-vessels, and from there to the transverse fissure of the liver, and the disturbance is apt to localize at the entrance of the portal vein, especially in cases of specific infection. There is one fundamental lymphatic law which can be adhered to, and that is that infection follows the lymph-vessels not into organs, but from organs toward other structures; also in all tubular structures, that is, in all ducts, in the body coming from glands this same law holds. You find them in the urethra and running to the bladder and the ureters to the kidney. Then, the lymphatic currents from the ductus choledochus run up to the hepatic duct and then to the liver, and those of the gall-bladder run through the cystic duct toward the common duct. Of course, it is possible that infection may be carried along this lymphatic system.

Every surgeon knows that these various regions are frequently related to one another. Often in operating for stomach or duodenal ulcer foci of infection are found in the appendix or gall-bladder, and frequently in the pancreas. Ochsner has reported that in 35 per cent. of his gall-bladder cases he has found an infected appendix. Kehr of Germany has removed the appendix in a large number of his gall-bladder cases.

As to the origin of duodenal and gastric ulcers, he believes that the theory of contact ulcer is very true. Contact ulcer is undoubtedly an embolic process. The work of Rosenow is rather conclusive as to the origin of these ulcers by the embolic process.

Up to about three years ago I was not a believer in the general statement made by many patients with duodenal ulcer that their attacks came on more particularly in the spring and fall. I have questioned many, and have found that duodenal ulcer is a disease more prevalent in the fall. Why is this so? The work of Rosenow is to some extent an answer. It is because of the possibility of a generalized infection in the body at certain periods of the year. Those due to the *Bacillus coli communis* probably will not be found to have any particular relation to any period of the year.

The same possibilities are present for infections of the biliary passages. There may be either a cholecystitis and a cholangeitis arising together, which is probably a frequent occurrence, much more so than we think, or the cholecystitis may follow the cholangeitis, or vice versa. The origin of these infections bacteriologically has been found to be due in the great majority of cases to two germs, *Bacillus coli communis* and *bacillus typhosus*. A Japanese observer has reported that 17.9 per cent. of his cases were due to other parasites instead of bacteria. The relation of gall-bladder disease to pregnancy I shall merely mention. It is probable than an element of biliary stasis in corset-wearing enters into consideration in these cases, because of the discrepancy of gall-bladder disease among Japanese women, 3 to 2 among men, and in Europe and America as 12 to 3 between women and men.

Another interesting point in connection with gall-bladder infection is incidence as regards advanced age. Old men are far more apt to have gall-bladder disease than the younger. At 70, the chances are even. That, of course, is due to the fact that the longer one lives the greater are the chances of acquiring some sort of infection.

The most common preliminary diseases which may lead up to trouble with the gall-bladder are: (1) typhoid fever; (2) influenza; (3) rheumatism, and then various forms of disturbance of the bowel, malaria, syphilis and peritonitis.

It is difficult to account for the spread of infection from the appendix to the gall-bladder; the portal blood is the only possible method, and it is only the chronic cases that produce this infection. There is one other possible source of infection, and that is a direct absorption of the blood-stream in the appendix, with consequent infection of the walls of the gall-bladder and liver directly. One point regarding the appendix: Chronic disease of the appendix does promote duodenal stasis, and with that you have an excellent chance for the development of a large number of germs; but the way of infection through the common duct and the liver I do not believe in at all. The simultaneous development of gall-bladder and appendix disease will probably take place, if it does take place, through the blood-stream. It cannot take place in any other manner. It is possible, but not probable, that infections of the gall-bladder take place by way of the portal tract. A great many men think that the infection is straight up the common duct. Dr. A. O. J. Kelly, in December, 1905, stated that infection does not, contrary to the opinion at that time, ascend directly from the duodenal and gastric area through the common duct into the liver, and there are good reasons for accepting this. Infection never takes place by bacteria going against the stream. If it cannot take place against the stream in the lymph-vessels, how can it take effect against the stream in cases of the ureter, or the common duct? It cannot do it.

Bond, of Leicester, England, has conducted a remarkable series of experiments which have been repeated and found to be true. He discovered that in vesical fistulas, indigo blue placed at the opening of the fistula below can be found afterward traveling up the urethra and appearing at the meatus. He said that it was not a capillary affair, because it did not appear in dead tissue, only in the living.

### Surgery of These Lesions

Dr. John B. Murphy: The experiments of Dr. Rosenow give us a new light, a clearing up of the connection between the primary infection manifestations and the secondary metastatic lesions. The surgeon's role in this class of case is necessarily small, but in 1902, when we first insisted that these arthritides were metastatic manifestations of infections in other positions in the body, it was considered very doubtful that that would be finally sustained; but we were positive, because there was such a clean-cut definite relationship in the cycle of metastases between the primary infection and the secondary manifestation in the way of an arthritic inflammation. When you see in a ward two, four, six, eight or ten of these cases with secondary joint manifestations, and in each case you can trace it back to practically the same position in the body, a chronic lesion of a definite type, you cannot fail to accept the primary lesion with the secondary lesion.

In the early fall we have our annual crop of spondylitides, each patient describing his attack in the same way, associated with types of infection of the same character, and giving fixation of the spine which looks as though the parts had been cemented together. The ossification which cements these bodies together is merely a continuation of the embryologic process of ossification in the joints of the long bones, and that deposit is taking place in the connective tissue. Finally, you have a solid, compact, bony mass, a complete ossification. All of that forced us to believe and insist that the primary lesion was an infectious one, and that the secondary lesion in the shaft was purely a metastatic manifestation of it. Then we asked ourselves, What rôle can the surgeon play? Dr. Billings has suggested to-night that the surgeon can restore the dislocated joints. That is not to be the rôle of the surgeon. We have insisted that the arthritides have a definite surgical local treatment. Furthermore, as the disease advances our limitations become more and more pronounced until there is nothing to do but the crude carpenter-work of reconstruction. But in the early stage of the disease there is a local treatment, a surgical treatment, and up to the time of the vaccine treatment it has been the only treatment that has availed anything.

What do you find on looking into these joints after an acute infective process has passed? Often just a local area of necrosis or ankylosis, no larger than a nickel. That is, in cases in which the manifestation is associated with an infection and the "rheumatism" is not initiated by a chill. When the "rheumatism" is initiated by a chill, which shows the virulence of the infection, whether due to a mutation of the diplococcus or to what we have no certain knowledge of, we have learned that an ankylosis in the whole of the joint is the rule, great enough to destroy, not the small area, but all that synovial membrane.

By means of experiments with the possible neutralization of the virulence of this material we are hoping to find some medicament which will destroy that, but until this is found let us take advantage of what we know in the way of stimulating phagocytosis. Thirty years ago Carlos by injections produced abscesses in different parts of the body which were known as concentrating abscesses. His clinical observation showed nothing at all about phagocytosis. He found that if, in an acute infection of the knee, in the hip or in some portion of the body a local abscess is produced, a rapid subsidence of the fever will result, and the patient will rapidly recover. What did that mean? It meant exactly what I can demonstrate any day, that injecting 20, 30, 40 or 50 minims of turpentine under the skin causes an abscess to form rapidly, and while it is forming there will be a great increase in general leukocytosis, and any infective process will be influenced by the formation of the abscess, which, you understand, is not a microbic, but a chemical abscess, which produces a constitutional leukocytosis.

What can we do in regard to the joints? Two things. We can stimulate the local resistance in the acute infections by producing an infiltration of the tissue within the joint. We can stimulate constitutional resistance by injecting into the joints something which causes not only a local increase in the polynuclears in the joint, but also a constitutional increase. During the inflammatory process the intra-articular pressure may be prevented by making extension. If we can do this, we shall stop the destruction in the joint or limit it to a very marked degree. We have demonstrated that again and again. Can we do this thing with the chronic varieties of infection? No. But we can do something with them. During the inflammatory process luxation must not be permitted to take place and deformity must not be permitted to occur. It is not necessary that deformities should occur. I feel that the treatment of joints is a prophylactic one, and not a therapeutic one—the joints must not be permitted to deform in the beginning, and then we shall not need to operate later to correct deformities.

## CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA

*Fourth Annual Session, held in Chicago, Nov. 10-15, 1913*

*(Continued from page 1929)*

### Further Observations on Chronic Intestinal Stasis

**Sir Arbuthnot Lane**, London: One case taught me how a patient may lead an active and happy life with only a small portion of the jejunum left after operation. In this case I removed a large portion of the jejunum, after which the patient gained rapidly in weight and strength. Several patients have attempted suicide on account of chronic intestinal stasis, and in all such cases the removal of the large bowel has restored the sufferer, not only physically, but mentally. In 106 cases in which I have performed the short-circuiting operation for chronic intestinal stasis, there have been four deaths.

### Relation of the Ductless Glands to the Work of the Surgeon

**Dr. Roswell Park**, Buffalo, N. Y.: The internal secretions, so often spoken of as hormones, exercise an apparently controlling influence on many of the organs and functions, not alone on the ordinary bodily functions, but also on the nutrition and regulation of individual organs and their particular activities, even to the extent of becoming responsible for the development of certain mental traits or personal characteristics which may make or mar the individual, and may thus affect both his physical and intellectual welfare.

The hypophysis is a persistent organ and, therefore, must have throughout life a continued function. Extracts of the whole gland increase blood-pressure, cause uterine contraction, increase peristalsis, lower carbohydrate assimilation, and have a mydriatic effect. Used to excess they cause emaciation, degeneration of the liver and increased metabolism. Extirpation produces in animals a peculiar cachexia, reduced pulse-rate and respiration, fibrillary tremors, and death from apathy and coma. The overgrowth of the pituitary sometimes occurring after typhoid is to be considered as the result of toxins which stimulate its growth, as well as perhaps that of the epiphyseal bony borders, thus accounting for excessive overgrowth after this fever. Something of the same kind is often seen after marriage, when the stimulation of the sex glands seems to extend in a short time to the hypophysis.

The thyroid was once regarded as a reservoir, by means of which blood-pressure in the brain was equalized. It seems to have an influence on the formation of the blood, slightly resembling the action of the spleen, possibly vicariating for it. Its most important task appears to be elaboration of iodothyrin. Certainly iodin is its most important constituent, and in this the thyroid is richer than any other organ.

The parathyroids have only within late years been given their proper consideration. It is generally believed that nearly all cases of tetany in man are of thyroidal origin, and due to defective function and consequent evidences of hypoparathyroidism. The thymus seems to have much to do with the development of the entire bony system; when its activity is reduced ossification is much interfered with, and sometimes it fails utterly.

### A Summing-Up of the Goiter Question

**Dr. Charles H. Mayo**, Rochester, Minn.: Various enlargements of the thyroid are the result of temporary excessive physiologic demands, as at puberty, pregnancy, infection, menstruation, etc. Many goiters of the simple and mild exophthalmic type undoubtedly recover spontaneously and, in many instances, various forms of medical treatment may hasten the recovery and restoration of the gland to an apparently normal condition. Simple goiters of long standing are often thrown into degeneration by giving iodin, causing thyrotoxicosis but not exophthalmos, although some symptoms are the same in these two forms of toxic goiter. Encapsulated adenomas and simple colloid goiters which have resisted treatment are in most instances best treated by removal of enough of the gland to remove the disease. In simple goiter the more enlarged lobe should be extirpated; encapsulated adenomas should be enucleated and thyroids which are bilaterally enlarged should have double partial resections with division of the isthmus. Exophthalmic goiter is essentially a disease chronic in character, presenting exacerbations and ameliorations of symptoms extending through a period of months or several years. While this disease is amenable to surgical treatment by the removal of a large part of the hypersecreting gland, this procedure should by no means be considered emergency surgery, and during exacerbations all cases should be considered medical. Surgery is indicated during the upward wave of improvement. Extreme conditions, especially dilatation of the heart, may require preparation medically before instituting operative interference, and this should be confined to a preliminary ligation of the left upper pole. Should reaction follow this, ligation of the right upper pole is indicated a week later and thyroidectomy reserved until the patient has gained in weight and general health. Otherwise thyroidectomy is made at a second operation.

6 [illegible] Diagnosis and Treatment, with Reference to Laboratory Methods. B. A. Thomas, Philadelphia.
7 *[illegible] of Case of Bronchial Asthma. L. F. [illegible]
8 [illegible] (Pseudohypertrophic Muscular Dystrophy in Combination with Degeneration in Central Nervous System). C. D. Camp, Ann Arbor, Mich.
9 *Two Instances of Chronic Family Jaundice. A. H. Hopkins, Philadelphia.
10 Clinical and Metabolic Studies of Case of Hypopituitarism due to Cyst of Hypophysis with Infantilism of Lorain Type (So-Called Typus Froehlich or Adiposo-Genital Dystrophy of Bartels). D. Stetten, New York, and J. Rosenbloom, Pittsburgh.
11 Diagnosis of Gastric Ulcer. J. R. Verbrycke, Washington, D. C.

**3. Dorsal Percussion in Enlarged Tracheobronchial Lymph-Nodes.**—The eighteen case histories taken as the basis of Da Costa's report were selected from a series of thirty-eight mediastinal cases which afforded definite vertebral percussion findings. They represent, he says, typical examples of these signs, depending wholly on the adenopathies in question and not on the limited pleuropulmonary lesions coexisting in a few instances. No case of enlarged bronchial lymph-nodes associated with some other large mediastinal mass (i. e., carcinoma, fibroma, gumma) has been included in the summary, in order to rule out, so far as possible, extensive neoplastic tumors as potential factors of the spinal changes noted.

The individual vertebral physical signs of the eighteen tracheobronchial cases are summarized and charted according to the following groups: 1. Interscapular dulness, above the level of the inferior scapular angles, or over the first seven thoracic spinous processes. 2. Intrascapular dulness, below the level of the inferior scapular angles, or over one or more of the five lower spinous tips. 3. General thoracic hyperresonance over the entire thoracic segment. 4. Normal percussion signs over the entire thoracic segment. In simple enlargement of the tracheobronchial lymph-nodes percussion of the thoracic vertebrae, especially above the level of the inferior scapular angles, usually affords tonal changes of real clinical value if properly interpreted. These changes, more often corroborative than primarily diagnostic, invariably should be correlated with the mural signs of the individual case.

Hyporesonance with maximum tactile resistance and hyperresonance with minimum tactile resistance, Da Costa claims, may have precisely the same significance in uncomplicated adenopathies. To explain this seeming paradox it is to be assumed that in the former instance the mass exerts a dulling pressure, and that in the latter it conducts the predominant tracheal tone. In nodular enlargements associated with pleuropulmonary lesions, emphysema and pleural adhesions are to be reckoned with as additional factors of hyperresonance and hyporesonance, respectively. In comparison with other (neoplastic) mediastinal masses, tracheobronchial tumors affect the vertebral percussion sound to a minor degree and more often produce dulness than hyperresonance. This general rule has a restricted clinical bearing in differentiating adenoid and malignant tumors. In routine examinations, Da Costa prefers ordinary mediate finger percussion to instrumental pleximeter percussion in studying vertebral changes of sound. The latter method, he says, gives no surer clue to tonal changes than that afforded by percussion with the bare fingers, and its practice obviously forbids all judgment of tactile resistance.

7. **Bronchial Asthma.**—In a patient with severe and repeated attacks of asthma seen by Warren, the pulmonary distention continued for several weeks after a cessation of a prolonged attack. This distention caused the heart to assume a vertical position, but did not influence its surface area. During the attack of asthma the diaphragm moved but slightly, and movements in reverse of the normal were observed. In explaining such reversed movements, however, one must take into account the excessive thoracic movements which act on the diaphragmatic attachments. The movements of these attachments may more than neutralize the movements due to the diaphragmatic contractions, so that the crests of the diaphragm may seem to execute reversed movements.

9. **Chronic Family Jaundice.**—A summary of Hopkins' cases is as follows: The jaundice was in every instance chronic, non-obstructive, and familial in type. In the first family, it extended over three generations, four members of which had had attacks of varying severity, and the attacks were more frequent and more severe in youth. The spleen was enlarged in each attack, at which times there was a moderate degree of anemia. Throughout the course of one case which Hopkins was able to follow more closely than any of the others, the fragility of the red blood-cells ran *pari passu* with the "bilious attacks" and the increase in intensity of jaundice. A second case did not show any increase in fragility, nor did the fourth case, both of which had been free of attacks for some time. The third case showed a lessened resistance of red cells up to 0.54 per cent. NaCl. The second family presented interesting features, in that three generations were involved and no less than five children in one immediate family were subject to the condition at that time. Owing to the fact that most of the family were living in Canada and New England, Hopkins has been unable so far to carry out further studies on the individual cases. In one point Hopkins' findings do not confirm those of Tileston and Griffin, as he has found in the serum of three members of this group isohemolysins to be present in ten out of a series of nineteen experiments.

13. **Stomach-Tube for Diagnosis.**—The unaided stomach-tube occasionally fails to detect gastric stasis which is demonstrable with the bismuth meal and Roentgen ray. Curious to determine the cause of this inefficiency of the stomach-tube, Harmer and Dodd were led to watch by means of the fluoroscope, the course taken by the tube. They observed in several individuals that the end of the tube did not pass directly to the most dependent portion of the stomach. In these cases, the tip of the tube first touched a portion of the stomach wall well above the most dependent portion. As more tube was passed, the end of the tube slid along the wall of the stomach a greater or lesser distance and became impinged against the stomach wall. On further passage of the tube, the end remained fixed and a downward bowing of the tube into the lower portion of the stomach occurred. This downward bowing of the tube apparently diverted the direction of force on the tip of the tube; for, as more tube was passed and the dependent loop of tube increased in size, the tip sooner or later slipped from its fixed position. The force on the tip was then upward through the dependent loop of tube and consequently the tip slipped upward toward the cardia; that is, it became further removed from any residuum which may have been present in the stomach. On passing still more tube, the end may follow about the wall of the stomach and may eventually reach its most dependent portion. They also observed, however, that it may again curve horizontally and then upward. The tip of the tube may skim the surface of the residuum and therefore drain only a portion of it. Further passage of the tube in the hope of reaching a deeper level of the contents may fail, because the tip may curve upward. The result in such cases may not be seriously deceptive. The degree of stasis may be underestimated, but the analysis of the siphoned contents may show stasis. In some instances, however, considerable amounts of residuum may entirely escape detection by the tube.

14. **Thrombosis.**—Different poisons, whether hemolytic in action or not, Aschoff maintains, bring about distinctive forms of capillary thrombosis, among which can be differentiated the following types: Blood-Platelet Thrombosis: This arises by intravenous injection of a homologous serum, of solutions of hemoglobin and stromata from homologous blood, of heterologous serums, ether, glycerin, distilled water, India ink, collargol and olive oil. The thrombi arise in the capillaries of lungs, liver and spleen. Thrombosis from Blood-Stromata: This occurs in pure form only, when very marked hemolysis occurs in the blood-stream as a result of the action of hemolytic agents. Otherwise it occurs only in conjunction with blood-platelet thrombosis. Thrombosis from Fragments of the Blood Elements (*Bluttrümmerthrombose*): Disintegration of the elements of the blood occurs by introduction of ricin, bacterial toxins, etc., which destroy the leukocytes, lymphocytes, macrophages of the spleen, liver and bone-marrow. The fragments, in conjunction with scanty fragments of erythrocytes, roll themselves together to form thrombi in the spleen and liver. Fibrin is then subsequently deposited there. Leukocytic Thrombosis: The polymorphic and mononuclear leukocytes phagocyte the foreign elements introduced into the blood-stream, and are stopped and held back in the capillaries of the internal organs, especially the lungs, spleen and liver, so that a leukopenia results in the peripheal circulation. This process is especially brought out by bacteria, but also by various indifferent foreign substances like particles of ink and starch. Fibrin Thrombosis: Although by injecting stromata or foreign serums the coagulability of the blood can be increased, no deposit of fibrin occurs. Deposit of fibrin occurs only secondarily, as a sequel of the types of thrombosis already described.

Aschoff claims that neither endothelial damage, on which so much stress was previously laid, nor a direct coagulation of the blood, play any rôle. Only two reasons for the thrombosis require to be considered, and their merits weighed one against the other; they are, the changes in the blood elements themselves, and the slowing of the blood-stream. Neither of these two factors can be excluded, as even in the experiments where thrombi of different sorts are produced by heightening the agglutinability of the blood-platelets by the disintegration of white or red corpuscles, these thrombi can occur only where normally a marked slowing of the blood-stream is present; for example, in the capillaries of the lungs, liver and spleen. But even by very marked destruction of the blood elements it is impossible to produce thrombi by deposition in the larger veins when no slowing of the current occurs. An additional factor, therefore, needs to be considered, especially in cases in which the thrombi are localized in the large veins, and where the above-mentioned capillary regions of the lungs, liver and spleen generally implicated in toxic thrombosis remain free. In such a case the increased agglutinability of the blood-platelets cannot be the direct exciting cause, but a definite and recognizable slowing of the blood-stream must first of all occur.

The slowing of the blood-stream and the alteration of the blood elements themselves, especially alterations of the platelets, are the chief factors in the production, not only of the static, but of toxic thrombosis. In static and similar types of thrombi the slowing of the blood-stream is of prime importance, while for the toxic varieties the changes in the blood elements have the dominating influence.

15. **Blood-Pressure in States of Excitement and Depression.**—Hawley found that cases of mania show typical features in the tracings which are taken, and these are probably due to an altered state of vasomotor tonicity in keeping with the other motor phenomena in these cases. These features are large amplitude of the curve, rapid action and short interval between beginning of the oscillation and full amplitude. The blood and pulse-pressures are raised and are more marked, as are the other features just spoken of, as the restlessness becomes more marked. All decrease as the patients recover. In non-productive cases these features are much diminished, but still demonstrable. Arteriosclerosis existing in maniacs raises the blood- and pulse-pressure still higher. The usual features of the maniac tracing are as apparent here as in cases without arteriosclerosis, and the larger amplitude, rapid action and early onset in the tracing are not features of the sclerosis, but of the maniac state. In cases of sclerosis occurring in other types of psychosis these features are lacking.

In stuporous cases the blood- and pulse-pressure are quite low. The amplitude is quite small and action is slow and tedious. This seems to indicate a condition of relaxation of the blood-vessels, in keeping with the other phenomena exhibited. In depressed cases the blood- and pulse-pressures are lower than in the maniac states, but higher than in the stuporous states. The amplitude of the wave, its onset and rapidity is less than in the manic states, but higher than in the stuporous states. Any rise in any of these things is due either to muscular resistance or physical disease and not to any state of mind.

In melancholia the average blood-pressure is relatively high, for the patients are among those in middle life. The blood-pressure and pulse-pressure are near normal as long as there is no muscular resistance, and no other factor, such as arteriosclerosis, to produce a rise. The tracings show nothing peculiar, except when these factors are added, and then blood-pressure is raised; the amplitude of the wave is also slightly increased. By taking many readings it may be possible to attribute high blood- and pulse-pressures in some cases to the varying effect of arterial and kidney disease on peripheral resistance rather than to the effect of the mental condition. In other cases resistance on the part of the patient is a factor in raising the pressure—a fact which might be overlooked had only one reading been taken at such a time.

16. **Age Incidence in Carcinoma.**—An analysis of over 1,100 microscopically verified cases of carcinoma by Weller showed that the incidence of carcinoma is greatest at the age period of 58 to 62. After this period the carcinoma incidence decreases. Carcinoma incidence in women runs a definite cycle which is roughly parallel to that in men, but precedes it by five to ten years. The earlier age for the phases of the curve for women is largely due to the earlier appearance of carcinoma of the breast and uterus as compared to other varieties of carcinoma.

17. **Heredity and Carcinoma.**—During eighteen years, 3,600 cases of neoplasm of all varieties were studied by Warthin either in material taken for practical diagnosis or obtained by necropsy. Of these 3,600 cases, some 1,600 were cases of carcinoma, as was shown by the microscopic diagnosis. About one thousand of these gave fairly good family histories with the ages of the members. A smaller number (30 per cent.) gave detailed histories. From this number are taken the families which show multiple occurrence of carcinoma. In many of these all of the members of the family for three generations are given; in others, the records are incomplete. Four families give complete records of the descendants of the cancerous grandparent. The incidence of cancer in these families is so striking that it can be interpreted as showing an inherited susceptibility to cancer.

Warthin believes that a marked susceptibility to carcinoma exists in the case of certain family generations and family groups. This susceptibility is frequently associated with a marked susceptibility to tuberculosis, and also with reduced fertility. The multiple occurrence of carcinoma in a family generation practically always means its occurrence in a preceding generation. The family tendency is usually more marked when carcinoma occurs in both maternal and paternal lines. Family susceptibility to carcinoma is shown particularly in the case of carcinoma of the mouth, lip, breast, stomach, intestines and uterus. In a family showing the occurrence of carcinoma in several generations there is a decided tendency for the neoplasm to develop at an earlier age in the members of the youngest generations. In this case the neoplasm often shows an increased malignancy. Because of the difficulty of obtaining complete family records, Warthin says, the laws of inheritance of carcinoma susceptibility cannot be determined accurately, and it is highly desirable that investigations of large family records should be made relative to the occurrence of carcinoma susceptibility. In Levin's study of cancerous fraternities in connection with the whole family history the percentage of cancerous members in each cancerous fraternity corresponds very closely to the Mendelian percentage of members with recessive unit-characters in a hybrid generation. The same conclusion might be drawn from Warthin's cases in certain instances, but it does not seem to him that the data are sufficient for such conclusions. He himself does not consider this conclusion as final. Levin also concludes that resistance to cancer is a dominant character whose absence creates a susceptibility to cancer. While some of Warthin's cases show a family history suggesting this, others would indicate a progressive degenerative inheritance—the running-out of a family line through the gradual development of an inferior stock, particularly as far as resistance to tuberculosis and cancer is concerned.

20. **Hexamethylenamin.**—The authors summarize the results of their work as follows:

1. The phloroglucin test is the most delicate and most useful test for free formaldehyd.
2. Alkalies prevent, while acids facilitate the liberation of formaldehyd from hexamethylenamin in all body fluids.
3. The liberation of formaldehyd from hexamethylenamin in pathological fluids obeys the same laws as in other solutions; that is, it can only occur in acid reaction. Even when 0.5 per cent. hexamethylenamin was added to them, not enough formaldehyd was liberated to be bactericidal.
4. Hexamethylenamin itself is not bactericidal.
5. Liberation of formaldehyd from hexamethylenamin depends on the excess hydrogen ion concentration of the solution above the neutral point.
6. Previous investigations leave us in doubt as to the behavior of hexamethylenamin in the body.
7. After administration, hexamethylenamin is present, but does not liberate free formaldehyd in blood, cerebrospinal, pleural, pericardial and synovial fluids, vitreous and aqueous humors, and urine when truly alkaline. Formaldehyd is liberated in urine which is truly acid, and in the acid gastric contents.
8. Administration of monosodium phosphate with hexamethylenamin renders the urine acid and facilitates the liberation of formaldehyd.

9. The administration of alkali with hexamethylenamin renders the urine alkaline and inhibits the liberation of formaldehyd.

10. The beneficial therapeutic effects of hexamethylenamin depend on the liberated formaldehyd. Such effects are to be expected principally, if not always, in acid urine only. It is irrational to prescribe alkalies (bicarbonate and citrate) together with hexamethylenamin.

22. **Cancer of Rectum.**—The operation of choice in cancer of the rectum in Jones' opinion is an abdominosacral, rather than an abdominoperineal operation. He has determined on a two-stage operation in a few of the cases. This consists in:

*First Stage.*—The inferior mesenteric is tied just below its junction with the aorta. The mesentery of the sigmoid is separated from the posterior wall, the ureters identified, and the rectum, with all the pelvic fat, is separated in one mass down to the tip of the coccyx posteriorly, while anteriorly it is separated from the bladder, or vagina. After separating the bowel in this manner, it is held forward and the peritoneal flaps brought together behind it. Instead of dropping the sigmoid back into the abdominal cavity, the upper portion is brought out through a rectus incision, and a Lilienthal colostomy done, great care being used not to injure the vascular arches in the mesentery. After twenty-four hours, the colostomy is opened and the distal portion cleansed by frequent washing, both from below and above.

*Second Stage.*—After five to seven days, the sacral portion of the operation is carried out as in the single stage operation. The sigmoid is cut off as high as possible in the pelvis, and the proximal end inverted and left as an appendage to the colostomy. Jones has carried out this two-stage operation with excellent immediate results in two cases. If the carcinoma is sufficiently high to make a resection and suture desirable, or if it is desired to bring the end of the sigmoid down through the sphincter, the inferior mesenteric should be tied in the usual way, and the whole sigmoid and rectum freed from the posterior wall and pelvis, as in a single stage operation.

The peritoneal flaps, which have been turned back, are then sutured together close about the freed rectum, and the abdomen closed. In from four to seven days, the posterior operation is carried out, the growth and a sufficient length of rectum above and below the growth is excised with the whole inferior mesenteric artery, and the fat surrounding it. An end-to-end suture is then done or the end of the sigmoid is brought through the sphincter. Jones is convinced that spinal anesthesia is essential in the combined abdominosacral operation, if the mortality is to be kept down.

23. ***Artificial Pneumothorax in Chronic Infection of Pleura and Lungs.***—After some experience with the method of artificial pneumothorax in the treatment of pulmonary pneumothorax, Floyd is struck with the relatively small number of those afflicted that are really suitable cases for this treatment. Well marked or advanced strictly unilateral cases are not especially common even in large clinics for pulmonary tuberculosis, and some observers believe that such cases are always bilateral. If this type of case is strictly adhered to, Floyd says, the results obtained where the method is carried out conscientiously will be uniformly good, and the percentage of patients markedly improved or even arrested will be as large as 40 per cent. or 50 per cent. If, on the other hand, as is the tendency with most men, almost any otherwise hopeless case in which satisfactory compression can be obtained, is given a chance of obtaining relief at least from persistent symptoms, the results will not be brilliant, and Floyd believes not more than 5 or 10 per cent. possibly of such cases will be arrested. Artificial pneumothorax, he believes, will be of real aid in the chronically recurring tubercular pleural effusion, and in some cases of bronchiectasis and pulmonary abscess in which the inflammatory conditions to be met are not too extensive. But even if this group of diseases may be benefited by the use of this method, its field in the treatment of diseases of the chest will still be relatively a narrow one. It is most applicable where the patient is under the supervision of hospital or sanatorium management, and has failed to do well with the older and well established methods.

26. **Series of Abdominal Cesarean Sections.**—Of the twenty-six operations performed by Fenton, sixteen were done because of obstruction to delivery owing to contractions in the bony pelvis; six were done on account of antepartum hemorrhage with undilated os; and one each for eclampsia at term, large baby, and stenosis of soft tissues; one case is unclassified owing to loss of history. Five cases were second operations on the same patient and two patients have subsequently delivered themselves unaided. All of the children were delivered alive and all but three left the hospital in good condition. The three died during the first two or three days from prematurity. One mother died, but it might fairly be claimed that her death was not due to operation. All of the cases might be classed as primary operations in that they were either done before the membranes had ruptured or before any attempts had been made *per vaginam* at delivery, or more than one or two vaginal examinations made and those under the strictest precautions

27. **Functional Diseases of Nervous System.**—Howland pleads that the terms neurasthenia and hysteria should not be used as diagnostic conclusions but should be entirely omitted, and that the general functional disturbances of the nervous system should be classified according to cause.

30. ***Regeneration of Bone.***—Ryerson's argument is this: If the periosteum were osteogenetic, then new bone would be produced beneath it over the area where it is stripped up from the bone and the osteoperiosteal angle would be one of the first parts to be filled up. That this is not the case, he claims, is manifested by his plates which show that the osteoperiosteal angle is actually the last part of the space to be filled with a shadow, indicating new bone formation. From this, therefore, his inference is that the periosteum is not osteogenetic in character.

54. **Amino Nitrogen in Tissues.**—Van Slyke's work was done as follows: The amino-acids are extracted from the tissues with hot water. Uncoagulated proteins in the extract are precipitated by alcohol. Alcohol and the slight amount of ammonia present in the extract are removed by concentration in vacuum, and the amino nitrogen in the residue is determined by the nitrous acid method. The rapidity with which the amino nitrogen reacts with nitrous acid, and the relatively small increase which it shows as the result of hydrolysis of the extract with hydrochloric acid, indicate that the amino nitrogen determined by the method outlined represents approximately the *free a-amino-acids*. Only a few per cent. of the amino nitrogen appears due to proteins or their intermediate products, and to amines not of protein origin. The correction for the latter can, when desirable, be readily determined.

56. **Transformation of Absorbed Amino-Acids.**—Van Slyke and Meyer show that the absorbed amino-acids (glycocoll, hydrolyzed casein, artificially digested flesh) disappear rapidly from the liver. The amino nitrogen content of this organ may be doubled by an injection of amino-acids into the general circulation, and yet return to normal within two or three hours. During the period required by the liver entirely to rid itself of absorbed amino-acids, their concentration in the muscles suffers no appreciable fall. From the other organs (kidney, intestine, pancreas, spleen) the absorbed amino-acids disappear less rapidly than from the liver, but whether as slowly as from the muscles has not yet been determined. The disappearance of amino-acids from the liver is accompanied by an increase in the urea of the blood. These results support the long contended view that the liver is the organ especially responsible for the catabolism of those protein digestion products not utilized for tissue construction.

The following explanation made by the authors as being consistent with the facts thus far ascertained. The amino-acids, with perhaps some peptides, from the intestine enter the circulation, from which they are almost immediately absorbed by the tissues. The power to take them up from the blood-stream is common to all the tissues, but is limited. The liver, however, continually desaturates itself by metabolizing the amino-acids that it has absorbed, and consequently maintains indefinitely its power to continue removing them from the circulation, so long as they do not enter it faster than the liver can metabolize them. When the entrance is unnaturally rapid or when the liver is sufficiently degenerated, as observed clinically in some pathologic conditions, the kidney assists in removing the amino-acids by excreting them unchanged. Death may result when the above agencies for preventing undue accumulation of protein digestion products are overtaxed. In regard to the synthesis of tissue proteins, the authors believe that, since each tissue has its own store of amino-acids, which it can replenish from the blood, it uses these to synthesize its own proteins.

58. **Influence of Salts on Growth of Rice Plant.**—The injurious effect of certain metallic ions on the growth of rice seedlings, Miyake says, may be perfectly counteracted only by the presence of calcium ions. Strontium ions can exert an influence only slightly retarding the toxicity of the metallic ions. Barium ion not only has no beneficial action, but a depressing effect is observed. Consequently, it is concluded that barium and strontium cannot replace the antagonistic action of calcium.

60. **Determination of Acetone.**—The author states that the Messinger method for acetone estimation gives correct results, whereas the Scott-Wilson method gives accurate results only when certain modifications in the original procedure are made. It is applicable to very minute quantities of acetone. Marriott found that in distilling a very dilute acetone solution, all of the acetone may be collected in the distillate within ten minutes.

63. **Endogenous Nitrogen Metabolism.**—Data are presented by McCollum and Hoagland which show that the endogenous metabolism of the pig reaches its lowest level when the animal has an abundant supply of carbohydrates together with a salt mixture of an alkaline character. The total output of nitrogen derived from endogenous sources can be greatly increased without changing the output of *creatinin*. The additional nitrogen which is eliminated on an acid over what appears on an alkaline diet is in the form of ammonia. The animal is not able to use the nitrogen of the urea fraction to neutralize the acids present in the diet, but draws additional nitrogen from the tissues for ammonia production.

64. **Idem.**—Feeding fat as the sole source of energy, it is claimed by McCollum and Hoagland, does not lead to a sustained rise in the nitrogen output of pigs which have been reduced to their lowest possible level of nitrogen metabolism by long continued starch feeding. Fat feeding may produce a considerable elimination of creatin. The total creatinin (creatinin + creatin) may be greatly increased without a corresponding rise in the total nitrogen output. The possibility of the acid or basic character of the ration having an influence on the creatin production is suggested.

65. **Idem.**—A considerable amount of the nitrogen which appears in the form of urea in pigs reduced to the endogenous level of protein metabolism, McCollum and Hoagland claim, may be converted into glycocoll when benzoic acid is fed, for the purpose of hippuric acid synthesis. When the quantity of benzoic acid ingested is not excessive, there is no noticeable rise in the total nitrogen excreted, over that which is eliminated on the same diet without benzoic acid. When the quantity of benzoic acid ingested is very large, there is a marked increase in the output of total nitrogen *catabolized*. The urea nitrogen cannot be reduced to a lower level than about 20 per cent. of the total. No change in the creatinin output is observed when the protein catabolism is stimulated by excessive doses of benzoic acid. Endogenous protein metabolism appears to consist of at least two types. One can be stimulated greatly for ammonia production by the introduction of mineral acids, or for hippuric acid when benzoic acid is introduced; the other, measured by creatinin, remains unaffected by methods described.

74 *Thrombosis and Occlusion of Lymphatics. E. L. Opie, St. Louis.

67. **Distribution of Vital Stains.**—The results of Levin's investigation seem to indicate that the vital stains when introduced into an animal with an inoculable tumor do not show any specific distribution which would show a predilection for the cells of the inoculated tumors. The organ cells surrounding the tumor contain the normal quantity of the vitally stained cells, while the tumor itself either contains none or very few such cells. It is of interest, though, to note that of the two tumors used in this investigation the carcinoma did not show any of the vital stains while sarcoma showed a certain amount. Levin suggests that a chemical may influence one kind of tumor and not influence another.

68. **Experimental Streptococcic Arthritis in Monkeys.**—Inoculations of cultures of *Streptococcus pyogenes* into the blood-stream of four monkeys induced a polyarthritis, suggestive in certain respects of "rheumatic fever" in man. In three instances immunity to the infectious agent was observed after repeated inoculations. The infecting organism could be recovered from the blood-stream at the onset of symptoms, but not afterward. This fact possibly has some bearing on the failure to isolate organisms from the blood of man with "rheumatic fever." Recovery from the induced arthritis may be complete and in such cases no lesion is found in the joint or periarticular tissues at autopsy. Repeated inoculations of streptococci induced a chronic arthritis in two cases, which was manifested by limitation of motion and contracture. In these affected joints there was found at autopsy thickening of the periarticular structures, thickening of the synovial membrane with fibroid infiltration and fringes of tissue growing into the joint which suggest villous formation. There was in one case also erosion of the cartilages. These lesions are analogous with those found in some types of chronic arthritis in man. Agglomerations of specifically staining cells were noted in the heart muscle, kidney, liver, spleen and periarticular tissues.

70. **Tubercle Bacilli in Feces.**—The authors briefly summarize their work as follows: Nearly all patients with tubercle bacilli in their sputum also have virulent tubercle bacilli in their feces. Very few persons who do not have tubercle bacilli in their sputum have acid-fast bacilli in their feces.

72. **Experimental Nephritis.**—Pearce and Ringer found that the administration to the dog of tartrates, by mouth, intraperitoneally or subcutaneously, causes a severe renal disturbance characterized by albumin and casts in the urine and diminished flow of urine or complete anuria. The urine passed before complete suppression is water clear of low specific gravity, and the solid constituents are greatly decreased. The most striking histologic change in the kidney is necrosis of the convoluted tubules, with fatty changes in the loops of Henle and sometimes also in the collecting tubules. Exudative glomerular lesions occur in about half the animals with severe tubular lesions. The mode of administration does not influence the character of the renal lesion, except in as much as diarrhea, following administration by mouth, may cause rapid removal of the salt from the intestine, and thus by reducing the amount of absorption prevent the severer types of lesion.

74. **Thrombosis and Occlusion of Lymphatics.**—A number of experiments were performed by Opie to test the effect of different tissues on the coagulation of lymph. He found that the slow coagulation of lymph is hastened by the addition of thrombokinase, and thrombosis within lymphatic channels occurs when thrombokinase is liberated by the tissues in the wall of the lymphatic. Necrosis of cells in contact with the lymph-stream favors thrombosis within lymphatic vessels by bringing thrombokinase into contact with the circulating lymph. After ligation of large lymphatic channels thrombosis may be caused by the injection of bacteria (*Bacillus pyocyaneus, Staphylococcus pyogenes aureus*) into the blood or by infection of the tissues in the neighborhood of the lymphatic channel. Occlusion of the thoracic duct or of large lymphatic trunks is followed by transient edema which is relieved in part at least by the establishment of collateral lymphatic circulation. After ligation of the thoracic duct flow of lymph into the vascular system may be reestablished within from two to four days: (a) by formation of a new channel entering the proximal part of the ligated duct, or (b) by collaterals freely joining the right thoracic duct; (c) in other instances no reestablishment of communication with the vascular system could be demonstrated but there was no widespread edema. Copious chylous ascites may follow occlusion of the thoracic duct in association with injury to a mesenteric lymphatic vessel. In a few instances continued diarrhea follows occlusion of the thoracic duct.

1. **Chronic Intestinal Stasis.**—It is Lane's rule to be satisfied with ileocolostomy if it is difficult to remove the large bowel, and to remove it if it can be effected easily. This is a very practical and convenient rule. He never performs gastro-enterostomy for duodenal distention even if there be ulceration, as it is both unnecessary and harmful. If, however, the ulceration has resulted in a considerable reduction of the lumen of the bowel, either by the great extent of the ulceration or because of its cicatrization, he employs a gastro-enterostomy, having first freed the ileal effluent by an ileo-colostomy, or by the other means already referred to. If the stomach be much dilated, because of chronic spasm of the pylorus, to such an extent that, after short-circuiting, the spasm cannot be met by washing out the stomach for several days, he performs gastro-enterostomy. If the stomach be ulcerated and there be no suspicion of cancerous infections in addition to a short-circuit, with or without colectomy, Lane does gastro-enterostomy, in order to take the strain off the lesser curve by draining the stomach very effectually. The only risk, Lane says, presented by the operations of short-circuiting and colectomy is that of adhesion of the intestines to one another, or to the abdominal wall, in such a manner as to produce a varying degree of obstruction. This is a risk common to all abdominal operations, and can only be reduced to a minimum by avoiding any unnecessary exposure or damage of the intestine, and by suturing the cut surfaces of peritoneum accurately together.

3. See *The Lancet*, abstract 29.

4. **Treatment of Spastic Paraplegia.**—The immediate objects of surgical treatment, Little states, are as follows: Correction of deformity, and abolition or diminution of spasm, with the ultimate end in view of enabling the patient to place the limbs in such a position that he may use them properly, but before undertaking any treatment the surgeon must form an estimate of the mental capacity of the patient. If this seems to be normal or even approaching to normal, it is worth while to undertake thorough and long-continued treatment, in the belief that the patient's will power and intelligence will enable him to take advantage of every improvement. If, however, the patient is idiotic, there is little hope of his learning to use his muscles, and disappointment is nearly sure to follow treatment. In a case of doubtful intelligence it is desirable to give the patient the benefit of the doubt, and to undertake the treatment, always remembering on the one hand that parents generally overestimate the intelligence of these children, and on the other that improvement in the physical condition is nearly always accompanied by improvement in the mental condition, sometimes to a surprising extent. Almost all observers are agreed on this point, and also in the opinion that treatment must be patient, prolonged and persevering.

5. **Hereditary Transmission of Sarcoma.**—Manson gives account of the illness and deaths of a mother and two sons from sarcoma, which he thinks justifies the title of his article.

6. **New Method of Dealing with Scars.**—The following method is described by Tubby: With a fine and strong-backed tenotomy knife a large number of multiple incisions are made transversely to the bands of keloid material. The incisions are placed close together, not more than one-tenth of an inch apart; and great care is taken that they should penetrate not only into the subcutaneous fat, but also extend one-quarter or half inch into the neighboring healthy skin. No attempt is made to arrest the hemorrhage except by pressure, and when bleeding has ceased, a solution of thiosinamin is vigorously rubbed in; and, if the scar tissue is very thick, a few drops are injected into the most prominent bands. Tubby has no hesitation in injecting, in children, 15 min. at a time, and in adults 20 min.; in only one case was there any effect on the heart. In that instance some slight cardiac collapse occurred for a few minutes; the patient, however, was over 60 years of age, and, happily, no permanent ill results followed. After the operation, the part is put up on a splint, in as much extension as possible, without tearing the soft parts, and is allowed to heal. This is accompanied by no excessive reaction and very little pain. After ten or fourteen days the wound will be healed, and the mobility of the part is increased by 50 per cent. The operation is then repeated, and, Tubby says, it rarely may be required three or four times. He has carried out this method in over a dozen cases, and has been specially pleased with the results.

29 *Visceral Complications Met with in Hysterectomy for Fibroids. J. Bland-Sutton.
30 Case of Hypophysis Tumor and Sellar Decompression. W. Harris and C. Graham.

29. **Visceral Complications in Hysterectomy for Fibroids.**—Fibroids, says Bland-Sutton, are often present in women suffering from chronic cardiac disease, and it has been maintained by several writers that uterine fibroids cause degenerative change in the muscular tissue of the heart. Many patients with fibroids have valvular lesions, a consequence of rheumatic fever, and in many women who have been reduced to a condition of profound anemia by a submucous fibroid the heart yields a loud murmur on auscultation. Bland-Sutton has had careful observations made on the cardiac condition of women with fibroids, and he says there is nothing which can be described as peculiar to the influence of these tumors. On a dozen occasions he has removed the uterus containing large fibroids, although the heart has furnished murmurs, clearly due to valvular lesions, when an examination by a competent physician has shown that compensation has been satisfactory and that an operation would not be attended with unusual risks. On three occasions he has removed a uterus containing fibroids from women who at the time of the operation possessed goiters and has been surprised on seeing the patients six months after hysterectomy to notice marked dimunition in the size of the goitrous thyroids. The presence of sugar in the urine, is, as a rule, a contra-indication to hysterectomy for fibroids. All patients requiring hysterectomy who come under Bland-Sutton's care have their urine carefully examined for sugar. Gall-stones are common in women; so are fibroids; and it sometimes happens that women come under observation with the two conditions giving so much trouble that the surgeon is puzzled to know which should be dealt with first. On three occasions Bland-Sutton has removed a calculous gall-bladder in the course of hysterectomy for fibroids. In each instance the uterus was so large as to require for its removal an incision reaching nearly to the ensiform cartilage. In these circumstances the removal of the gall-bladder was a simple operation. In one instance the inflamed gall-bladder adhered to a large subserous fibroid. In two other instances of this combination he removed the gall-bladder six months after the hysterectomy. The only definite rule which he thinks can be laid down in the matter is this: If a woman deeply jaundiced in consequence of a stone impacted in the common duct also suffers from a uterine fibroid, which so troubles her as to make it desirable to remove the uterus, he should prefer to remove the stone from the common duct first because it is well known that cholemia predisposes to hemorrhage. Hysterectomy in a woman with persistent jaundice is an operation which would place her life in the gravest peril from post-operative bleeding.

37. **Nauheim Treatment in England.**—The post-influenzal heart, weakened and dilated by the toxins of the disease, and giving rise to symptoms of dyspnea, palpitation and cardiac pain, and ultimately causing a general invalidism and inability for any work or pleasure, Thorne says, is one which responds rapidly to this treatment. Cases of high arterial tension, in which the area of cardiac dulness is found to be enlarged, exhibiting symptoms of dyspnea, headache, palpitation, cyanosis and general ill-health, will respond well to a course of Nauheim baths, and the blood-pressure will drop from 20 to 40 mm. Hg during treatment, often falling from 170-80 mm. Hg to 130-40 mm. Hg, and the troublesome and dangerous symptoms will be relieved for a long period. Cases of valvular disease with cardiac dilatation, indicating a weakened and degenerate condition of the myocardium, respond well to the treatment, more especially if high arterial tension is present. In uncomplicated cases of valvular disease with cardiac hypertrophy treatment is not necessary, but it is seldom that a case of valvular disease of long standing with a raised blood-pressure does not exhibit some symptoms of cardiac dilatation and defective circulation, and if these are present they can be relieved by a course of baths more satisfactorily and for a longer period than by any other form of treatment. When premature cardiac contractions, arising in the ventricles or auricles, are present, causing cardiac irregularities and distress to the patient, it is often found that they gradually decrease in frequency during a course, and that at the end of the treatment a perfectly regular heart's action is established, this being due to the improved nutrititon of the conductive mechanism of the heart. Cases of obesity and fat-clogged hearts and raised blood-pressure are not only greatly improved in health by a course of Nauheim baths, but lose fat steadily both during the course and for some months after.

Cases of irritable heart of a "functional" nature, in which no organic lesion is discovered, are often greatly relieved by this treatment, but they are not so certain of improvement as cases in which definite dilatation is present. Cases of anemia with cardiac dilatation, which do not respond to treatment with iron, arsenic or general hygienics, will often show immediate improvement if a course of Nauheim baths is given in conjunction with other treatment. Thorne states that it is not advisable to give the Nauheim treatment in cases in which there is general evidence of a broken-down constitution, nor has he found it of much benefit to patients exhibiting auricular fibrillation, or in those in which very advanced degeneration of the vessel-walls is present.

63 Physicians in Decameron. J. B. Adams.

47. **Widal's Agglutination Reaction.**—The main point made by Scott is the value of the agglutination reaction as an aid

in prognosis. If the case is "clinically typhoid" but no agglutination is obtained by the tenth day, Scott says, the case is likely to be severe and prolonged. Not uncommonly a hemorrhage in these cases will, within a few hours (provided it is not fatal), be followed by a marked rise in the agglutinating power of the serum. Scott is inclined to think that in some of such cases benefit would result, if nature were to be forestalled by a small quantity of blood being withdrawn by venesection, and the agglutinating power of the serum thus raised.

57. **Cardiac Conductivity.**—Thorne cites cases to show that the action of Nauheim baths on cardiac conductivity and muscle contraction is very beneficial, for it not only accelerates a slow, and regulates an irregular conductivity, but markedly stimulates auricular contraction.

59. **Is Enlarged Prostate Cause of Residual Urine?**—The question asked in the title is answered by Miller in the negative because he has seen cases in which there was enlarged prostate without any residual urine, and others in which there was residual urine without any perceptible enlargement of the prostate. In patients who present themselves for treatment, especially at hospitals, the two conditions usually co-exist. Miller submits this might be because both conditions are common in old men. If each occurs sometimes separately, surely neither can be considered the invariable cause or result of the other. They cannot be mutually inter-dependent. In Miller's opinion residual urine is the result of an acquired habit of not emptying the bladder thoroughly. No doubt an enlarged prostate, by making micturition more difficult, increases this habit or may start it. But, that "habit" is the explanation is Miller's conviction, because residual urine can be got rid of by training the bladder to empty itself thoroughly even when enlargement of the prostate is present.

67 *Obesity in Children. P. Le Gendre.

67. **Obesity in Children.**—Le Gendre's article has already been mentioned in The Journal, November 8, p. 1739. He emphasizes that obesity is a progressive syndrome from changes in the functioning of the nervous system regulating the deposits of fat; these disturbances are the result of the action of toxins from within or without. The obesity is first a symptom, then a syndrome, and then a disease, and it is important to arrest it in its early phases. Obesity may be regarded as physiologic in a breast-fed infant with good general health; the weight generally returns to the normal standard after the child begins to walk. There is also a physiologic obesity just before puberty which the children outgrow. Under all other conditions he regards a progressive increase in fat under ordinary circumstances as a sign that something is wrong and requires correction; *if not corrected, other functional disturbance will* develop not dependent on the obesity but on the nutritional anomaly of which the obesity is only one manifestation. An inherited predisposition is evident in the majority of cases; such children generally belong to families of large eaters through several generations, and the obesity in the children can be traced to this gouty, neuro-arthritic inheritance with sluggish elimination. He discusses the influence of the glands with an internal secretion, and says that the importance of correcting the causes entailing obesity in children is enhanced by the fact that the obesity prevents the child's taking part in the plays of its mates. Treatment should aim to correct the errors in hygiene and diet and the insufficiency of the thyroid, genital or other glands involved. The table in certain families, he remarks, seems to be planned to bring on obesity, or the children are given beer or wine which injures their digestion and nervous system. In certain families the parents demand too much of the children so that they reach school wearied and worried over their tasks and lessons, their walk to school interfering with digestion. Then they are liable to play too hard and exhaust themselves and forget to go to stool at regular hours. He thinks that walking may be carried to excess for children; their bones are not fitted for prolonged regular walking. It is valuable only in small doses, but *a few minutes of exercises* and games which have a tendency to increase the ventilation of the lungs are particularly useful. The great difficulty in the family is that the parents like to see the child eat and fear "it is not getting enough."

68 *Operative Treatment of Infectious Processes in the Palm of the Hand. R. Picqué.

68. **Infectious Processes in the Palm of the Hand.**—Picqué describes with fourteen *illustrations the best technics for* operating on infectious processes in muscle or tendon sheaths in the palm. Eight of the illustrations are devoted to the *normal anatomy* of the region at different depths. For a phlegmon in the palm, he makes two incisions, radiating from the center of the palm near the root of the thumb, but for suppuration in the tendon sheaths he makes four, one along the ball of the thumb, the second an extension of this along the front of the thumb. The third incision runs at a right angle from the first and reaches nearly to the root of the little finger. The fourth is the extension on the palmar aspect of the little finger of the third incision. By this quadruple incision, total suppurating palmar synovitis can be reached and treated without injury of the vessels. The two incisions run parallel to the vessels, but they are on the flank of the flexors and thus the vessels can be readily detected and drawn aside at need. The four drains introduced should converge toward the pus pocket but they should never be pushed forcibly in. He has seen the temperature drop from 104 to normal by the next morning after this quadruple incision which ensures transverse drainage on both sides. In case the trouble persists, from involvement of the wrist region, he divides the annular ligament after suturing the four incisions of the day before. No functional disturbances follow section of the annular ligament, while it permits ideal drainage of the region. If a phlegmon develops in the forearm, the two lateral incisions below should be carried up as needed. If the wrist proper suppurates, the dorsal incision according to the Ollier or Kocher technic, supplementary to the incisions in the palm, will permit X drainage. In one case *he successfully performed all the above operations in* turn in the course of forty-eight hours, an insane man having cut himself by breaking a window. Lecène cuts the annular ligament as one of the first steps, but Picqué advises the above sequence, restricting the intervention to what is actually needed at the moment.

73 Urethroceles in Men. J. Paris and A. Fournier.
74 Irrigation of the Urethra without a Catheter. (Technique des lavages sans sonde de l'urètre.) J. Janet.

69. **Suprapubic Prostatectomy.**—Marion declares that the care after the operation is responsible for the ultimate outcome far more than the operation itself. Everything should be done to hasten the healing of the wounds and restore normal conditions in the bladder while keeping the general condition good, constantly *on* the watch to avert complications. He drains by means of a broad right-angled tube with small tube attached to permit irrigation of the bladder. The recess left by removal of the prostate is packed loosely with gauze to which two threads are firmly fastened, the ends of the threads brought out through the broad glass-drain. The drain tube must reach deep down into the bladder to ensure

perfect draining; as the wound heals the tube is replaced with one of smaller diameter. The part reaching into the bladder is the same length in all. Some of his patients had the bladder heal in twelve days, others not until twenty-five or thirty days. The retention catheter must be kept in place nights for two nights after the bladder has healed, to avert distention during sleep. The less the parts are handled, the less danger of complications. He insists that the postoperative measures should be applied by the physician himself, unless he has a dependable nurse with long experience in exactly these cases. By taking charge of these minor details, the physician is kept in close touch with the patient and can detect and remedy unfavorable conditions at their first manifestations, while he is constantly learning new points in treatment which can be applied at the time and later.

71. **Advantages of Nephrostomy.**—Pakowski concludes his long article on this subject by emphasizing the importance of proceeding gradually, never attempting too much at one sitting, in operations on the urinary apparatus. A preceding nephrostomy on both sides, diverting the course of the urine, leaves the field below free for any operation that may be required. The mortality to date has been only 4.5 per cent., and in these cases the fatality was due to the affection for which the nephrostomy had to be done rather than to the nephrostomy itself. Implantation of the ureters in the skin, urethra, vagina or bowel has a high mortality at the time and from pyelonephritis later. Nephrostomy permits direct treatment of lesions in the kidney; it also permits restoration of the natural course of the urine later, while it drains the kidneys most effectually, and this is the only means of warding off ascending infection. Ureterostomy is its only rival, but this does not drain the kidney so well.

He reviews 119 cases of total cystectomy; sixty-seven patients did not survive the operation, the mortality thus being 56.3 per cent. The gravity of the prognosis in these cases is due to the unwise method of caring for the ureters. Four died at once of the five patients whose ureters were implanted in the urethra; nine out of sixteen soon died when the ureters were implanted in the vagina. The mortality was 67.2 per cent. in the fifty-five cases in which the ureters were implanted in the bowel. All these fatalities are due to shock, anuria, peritonitis or ascending infection—all of which is the result of the laborious technic of the implantation procedure or of defective sutures. The fatal factor in this high mortality is generally pyelonephritis; it may have existed prior to the operation, and this is an additional argument in favor of preliminary nephrostomy. This is the only means to estimate conditions in the kidneys and improve them before proceeding to the cystectomy or other operation below. The benefits of this are instructively shown in two cases related in detail: In the first preliminary bilateral nephrostomy was done ten days before the bladder was entirely removed for cancer. The general condition is very good to date, nearly a year since the operation. The nephrostomy was also intended to be permanent in the second case in which the bladder and prostate were removed for epithelioma; the man of 53 was a worker on anilin dyes. The first symptoms of trouble had been severe recurring hematuria. There was no shock after the cystectomy, but rebellious hiccough for a few days followed both the nephrostomy and the cystectomy. Pakowski regards double nephrostomy as indicated with all malignant, painful and rebellious affections of the bladder, as also with congenital malformations, and with affections of the pelvic organs invading the bladder or compressing the ureters; also in case of a persisting tendency to production of calculi in the kidneys. Nephrostomy may be the only means to correct nephrolithiasis. Nephrostomy may also be indicated as a preliminary to treatment or operation for traumatic lesions of the lower urinary apparatus, especially vesicovaginal fistula. The nephrostomy may be only temporary in these cases. Nearly twelve pages of bibliography are appended.

72. **Tuberculin Treatment of Renal Tuberculosis.**—Gauthier reports the end-results in a case of renal tuberculosis which he published last year as an instance of successful tuberculin treatment. Nephrectomy became necessary a few months later. This has destroyed his confidence in tuberculin treatment, as this is his fourth failure with it. He found it valuable in two other cases, in one of which both kidneys were involved, rendering nephrectomy impossible. His conclusions are in harmony with Albarran's dictum, *Diagnostic précoce, néphrectomie précoce.*

81 Experimental [illegible] Ovaries. A. Lacassagne.
82 *Stretching or [illegible] Nerves in Painful Arterial Affectic[illegible] R. Leriche.

75. **Operative Treatment of Trigeminal Neuralgia.**—De Beule insists that resection of the root of the trigeminal nerve between the gasserian ganglion and the protuberance answers all the purposes of gasserectomy while it is a much simpler and safer operation. It does not destroy the nerve route but breaks its continuity by taking out a segment. He says that the nerve here is composed exclusively of white fibers, and white fibers once degenerated never regenerate anew, and consequently no transmission of pain is possible later, while the ganglion and the rest of the nerve are left intact. De Beule credits the method to Spiller of this country, but says that Van Gehuchten's research first rendered it practicable. All his eight patients have been permanently cured by the operation, and no by-effects have been observed. This technic has been applied in seventy cases to date, to his knowledge; two patients died. In one of De Beule's cases the patient died several months later and necropsy revealed a large cancer originating in the sphenoidal sinus. The pressure from the growth had evidently been the cause of the "neuralgia," but the patient was freed from pain thereafter by the neurotomy. This case is cited as strikingly confirming the theoretical premises on which the retrogasserian neurotomy is based. Seven plates accompany the article illustrating the technic and the ample access and oversight afforded by turning down a flap directly over the ear. The guide is the anterior surface and the upper margin of the petrous portion of the temporal bone, and this must not be forsaken on any pretext. The outer edge of the nerve is always found just inside the retrogasserian tubercle.

76. **Malignant Degeneration of Benign Tumors of the Breast.**—Jaboulay ascribes to invasion by a protozoon the transformation of benign mammary tumors. The sarcosporidia involved are not found in the same phases of development as in animals, but the cancerous degeneration follows on their trail. He gives eight illustrations of sporoblasts and spores found in a testicle sarcoma; *sarcosporidia in a thyroid cancer;* spores in a mammary tumor, showing patches of malignant degeneration, cystic disease, etc.

78-82. **Stretching the Perivascular Nerves for Painful Arterial and Other Disease.**—Leriche and Dufourt report four cases of tabetic gastric crises in which they applied stretching of the solar plexus. They state that the procedure caused no inconveniences of any kind and the immediate results were excellent, but they did not prove durable. They think that the principle is good, but that the technic to date is still defective. Leriche ascribes the failure in tabes to the fact that the lesion of the nerves is too diffuse and wide-spread to be affected by the operation. On the other hand, it offers every prospect of success in certain cases of intestinal pain of arterial origin which may be defined as Raynaud's disease of the intestine, as also in painful subacute aortitis. The spread of the inflammation to the nerves around entails intense pain, liable to elicit fatal reflex action, vasomotor spasm of the coronaries, cerebral arteries or bronchial vessels. Other affections possibly amenable to this treatment are true Raynaud's disease and congenital trophoedema. In a case of the latter, Leriche states that the leg became reduced 2 cm. in circumference after denudation of the femoral artery in the triangle of Scarpa. Jaboulay has found this useful in treatment of rebellious mal perforant; Viannay has been equally successful with it, and Leriche in two cases. In one of his cases the affection returned a few months later, but the healing proceeded rapidly afterward. The aim is to stretch the perivascular plexuses, dilacerating the peri-arterial plexus. He calls the procedure "denudation of the artery and dilaceration of the perivascular nerve plexuses." The disturbances he seeks to remedy by this may not be the only elements in the clinical picture, but excluding these may transform the whole syndrome. The nerve ramifications may be involved in inflammatory sclerosis, and there is every reason to liberate them.

87 Lymphogranuloma in the Mediastinum. Wanner.
88 *Tetanus of the Head. (Le tétanos céphalique). J. Mégevand.

85. **Classification of Mental Diseases.**—Schnyder thinks that in all the fluctuating conceptions of nervous and mental diseases the conception of psychasthenia, as Dubois formulates it, supplies a solid foundation for classification and treatment. This conception defines psychasthenia as a weakness in the primary judgment of things and events. Psychonervous disturbances can thus be traced to the habitual mentality. Effectual treatment, therefore, consists in rendering the judgment saner, bringing the individual to a juster appreciation of things and events.

88. **Tetanus of the Head.**—There was no history of trauma, and the young man had been previously healthy when the tetanus developed with facial paralysis and trismus. The reflexes were exaggerated but three were no other symptoms except that the larger muscles were slightly tender and showed a trifle of contraction. He was given chloral in large doses, 12 gm. a day for thirteen days. Then the chloral was suspended for two days, but aggravation of the symptoms and pain in the legs caused its resumption. Within fifty-one days he was given 456 gm. of chloral with final recovery. The disease evidently increases the tolerance for the drug. The mortality of tetanus of the head is only 36 per cent., according to recent statistics.

### Semaine Médicale, Paris

89 *Automatic Reflex Movements. (Réflexes d'automatisme médullaire et réflexes dits "de défense"; le phénomène des racourcisseurs.) P. Marie and C. Foix.

89. **Automatic Reflex Movements.**—Marie and Foix have been studying the reflex movements which occur after the brain has been cut off from communication with the limbs, as in decapitated frogs. They conclude from their research that these reflex movements are not for the purpose of defense but are mainly the automatic movements of locomotion. The limbs are drawn up as in walking, the spinal cord functioning automatically when the brain is cut off. The reflex flexing of the limb is thus a sign of injury of the pyramidal tract. This assumption was confirmed at necropsy in three typical clinical cases. The reflex movements are generally moderate when the pyramidal tract is not much affected, but they become extremely pronounced when all the conducting routes are interrupted more or less completely, as by transverse myelitis or with paraplegia from compression. The tendon reflexes are exaggerated in the former, and the reflex automatic gait movements in the latter. These reflexes can even locate the site of the lesion in some cases. Study of them shows the connection between isolated facts which have hitherto seemed incomprehensible separate phenomena. These automatic, falsely styled "defensive" reactions fit into the great group of sensory-motor reflexes; they show the close connection between human pathology and experimental physiology and throw new light on the complex problems of reflex action and contractures.

100 *Tuberculosis in Prussia since 1876. R. Behla.

90. **Scarlatinal Heart and Kidney Complications.**—Baginsky reports some cases and expatiates on the benefit from sweating procedures in the moderately severe cases. They not only arrest by mechanical means the congestion and tendency to suffocation from the hydrops, but they relieve the heart and respiration by the diuresis induced. A typical case is described in which the temperature was 105 at first but dropped at once after venesection, and the sweating procedure completed the change for the better. When the temperature keeps high, these hot sweating procedures are contraindicated as fraught with too much danger, and cold packs should be given the preference, leaving the child for an hour or two to sweat in the cold pack. In a typical case reported, a month after scarlet fever, the symptoms of uremia, dilatation of the heart, hydrops, high fever and severe dyspnea, subsided under the cold pack in which the child, a little over 3 years old, was left to sweat for a time. It seemed to have a direct life-saving action. He does not advise but one such pack a day, and he warns that as children react more vigorously to therapeutic intervention than adults, the pediatrist must be even more cool and cautious than at the bedside of adults.

96. **Mercury for Immunization of the Blood Against Septic Disease.**—Krohl noticed that patients taking a course of mercurial treatment seemed to be peculiarly resistant to ordinary infectious diseases, especially to epidemics of cholera, in his practice at Kiev. This fact and others suggested that mercury might have an action on the blood rendering it immune to septic processes, and his experiments with seventy-eight rabbits apparently confirm this assumption. He found that rabbits injected with mercuric benzoate (hydrargyrum benzoicum), bore without harm the injection of serum from the blood of a woman who had died of puerperal fever, or injection of pure cultures of streptococci. The doses of the mercury were very small; a series of injections of 0.0015 gm. to 1 kg. of the body-weight rendered the animal non-susceptible to infection with streptococci. A shorter series with a little larger dose also answers the same purpose. The drug showed such efficacy in the animals that he applied the same treatment to a number of patients threatened with septic processes, and reports a few typical cases to show the efficacy of intramuscular injections of this drug in prophylaxis of sepsis. Once developed, the septic affection is not modified by the small doses which he recommends. Among the illustrative cases cited is that of a woman of 29 who had chills and temperature of 39.1 C., pulse 128, the skin dry and the patient very restless and extremely thirsty, the third day

after delivery. She was given three injections of 0.01 gm. mercuric benzoate in the course of three days, under which the temperature and pulse subsided to normal. In another case with about the same symptoms after an artificial abortion, the mercury was not commenced until after the fourth day, and the patient died. Krohl regards these experiences as showing the importance of sterilizing the blood in this way while it is still possible to effect this.

100. **Tuberculosis in Prussia According to Age.**—Behla gives diagrams showing the mortality from tuberculosis according to ages since 1876. The total mortality has dropped from 30.95 per 10,000 living, in 1876, to 14.58 in 1912. Between the ages of 15 and 30 the decline has been from 26.91 to 17.48; between 30 and 60, from 48.62 to 19.49, and over 60, from 77.62 to 19.81. For children under 15, the decline has not been so great: Under 1 year of age the mortality was 22.24 in 1876 and 18.4 in 1912; between 1 and 5 years of age the figures are respectively 11.72 and 8.22; between 5 and 10, 4.17 and 4.32 and betecwn 10 and 15, 5.71 and 5.21. This lack of decline in the mortality from tuberculosis among children is remarkable when we consider that the mortality from other diseases among children has dropped so materially for the same ages. Diphtheria, for instance, from 45.09 to 6.98, and typhoid from 5.29 to 0.28. The figures for 1908 show that 1,423 of 2,852 infants succumbing to tuberculosis died in the first six months and 1,429 in the rest of the year. If congenital tuberculosis were very prevalent the proportion succumbing in the first six months would have been larger.

103. **Radiotherapy of Cancer.**—Freund emphasizes that the same rules apply to radiotherapy as to operative treatment of cancer, namely, that intervention should be as early as possible, before the lymph and blood-vessels have become involved and before long offshoots have been sent forth. When the technic becomes so perfected that all the cancerous tissue can be effectually destroyed by the rays applied from all sides, then radiotherapy can be regarded as a certain cure for cancer. Until these conditions are realized the rays have only a narrow field of action, and radiotherapy thus represents merely a painless and elegant method of palliative treatment: The cancer germs left, not destroyed by it, bring on recurrence with possibly even a more rapid course than the first time. It is impossible to say beforehand whether the rays will reach and destroy all the cancer cells, although this is always theoretically possible. He adds that even if the cancer is entirely cured by the radiotherapy, this does not guarantee that another cancer may not develop at some previously sound point, in the sound breast, for instance. Preceding removal of the pathologic tissue will naturally enhance the action of radiotherapy later. He thinks that the dosage in milligram-hours is not very scientific. The dosage should be calculated for the quantity of the radium element present, the length of the exposures, the mode of filtering, the superficial and deep extent of the cancer, and its histologic and physical character. His conclusions are based on 176 cancers treated by the Roentgen rays or radium in the last twelve years in Finger's service at Vienna. The best results were attained in case of epithelioma, ulcus rodens and Paget's disease. Thirty-two of the eighty patients in these categories have been cured for from one to ten years, that is, 35 per cent.

104. **Benzol in Leukemia.**—Mühlmann reports a case of lymphatic leukemia in a man of 37 with necropsy findings. He was given benzol during nearly six months to a total of 175 gm. There was marked improvement at first; after three or four weeks the condition was much improved and the condition continued to improve on suspension of the benzol for two weeks; then the leukocytes began to increase in numbers again but a further course of 40 gm. benzol reduced the leukocytes to 20,000. Then they ran up again and the patient succumbed. Necropsy showed extensive necrosis in the liver. Neumann has reported similar findings of necrosis in the liver of a man with myeloid leukemia treated with benzol. Pappenheim also found necrosis in the liver of rabbits given benzol, although in the rabbit liver the necrosis was in the outer portions; in the two clinical cases it was in the central part. These experiences emphasize the wisdom of keeping close supervision over the functioning of the liver during a course of benzol treatment.

112 Prophylaxis of Recurrence of Cancer. A. Theilhaber.

110. **Polyserositis.**—Esau operated for a supposed abdominal tumor in the case reported but no tumor was found, merely an enormously enlarged liver, with ascites. The liver tissue seemed normal and there was no pathologic history, no syphilis. However, a tentative course of antisyphilis treatment was instituted but no effect from it was apparent. The man of 28 soon required tapping and fifteen liters of fluid were siphoned out. During the three following years the patient had to be tapped at first every four months but later more frequently. Omentopexy was done (Talma operation) the fourth year but with only transient benefit. The necropsy findings after eight years showed typical polyserositis, iced liver and spleen, and chronic obliterating pericarditis. Tapping had been repeated eighty times and a total of 800 liters of fluid had been withdrawn. The man had been previously healthy except for typhoid at 11, and he had three healthy children. The second patient was a previously entirely healthy man of 49 and the disease ran an acute course in two months. The characteristic findings were restricted to the small intestine, causing multiple stenosis and agonizing colics. A laparotomy showed the small intestine enormously distended, with the characteristic iced appearance, the result of chronic peritonitis without effusion. The man died in collapse the second day. No signs of tuberculosis were found in either case. There seems to be no help for polyserositis except from operative measures and these usually come too late. The hope lies in some modification of the Talma operation—omentopexy—done before irreparable lesions have become installed. The trouble generally begins with a stormy onset and then passes into a chronic phase with recurring ascites, gradual weakening of the heart, edema of the legs and cyanosis. The patients are generally under 30 but middle age is not exempt.

116 *Diphtheria Antitoxin Content of Human Blood Serum. *H. Kleinschmidt.*

115. **Transillumination in the Diagnosis of Chronic Internal Hydrocephalus.**—Strassburger in 1909 demonstrated hydrocephalus in a 3-months-old child with head of practically nor-

mal size. He had examined it under strong electric light in a dark room and had found the skull transparent. This transparency is present only when the thickness of the brain substance is not more than 1 cm. The bones of the child's skull are transparent under strong light, up to about the age of 3. Von Bokay gives histories of fifteen children with internal hydrocephalus whom he examined in this way. The degree of transparency depends on the thickness of the brain substance and the amount of fluid. The collection of fluid is frequently asymmetrical and the method gives information of practical value as to where puncture and drainage can be done most effectively and with least injury to the brain substance. It is particularly valuable in the diagnosis when the size of the head is almost normal and gives little or no indication of the condition. The findings in his cases are shown in eight colored plates.

116. **Diphtheria Antitoxin in Human Blood.**—Kleinschmidt concludes that the diphtheria antitoxin so frequently found in the serum of individuals who have not had diphtheria is due to latent infection with diphtheria bacilli. Protective substances must have been formed in sufficient quantity to avert an attack of the disease. He found antitoxin in the serum of two of eighteen infants free from any history of diphtheria, and in ten of sixteen others known to have had diphtheria up to a few months before and still harboring the bacilli. Technical details of his experiments are given.

123 Kaolin-Glycerin Paste in Dermatology. P. G. Unna. Commenced in No. 41.
124 Döhle's Leukocyte Inclusion Bodies Not Peculiar to Scarlet Fever. M. Massini.

117. **Treatment of Thrombosis and Gangrene.**—Lotsch recapitulates the general view that the treatment of thrombosis lies essentially in prophylaxis. Passive exercise and light massage should be systematically applied to persons kept long in bed for any cause. With gangrene, the aim should be to ward off putrefaction. The surface should be kept dry with powder or superheated air, but he warns that the resistance of the tissues to heat is materially reduced, and great caution is required. Reports are accumulating of favorable results from local alternating hot and cold baths, changing from the hot to the cold water and back again repeatedly for fifteen minutes at a time. The alternation of anemia and hyperemia thus induced causes a gymnastic exercising of the vessels, and if kept up for a long time, up to several months, may realize great improvement. He says that fifteen cases are on record in which an attempt was made to extract the embolus in the pulmonary artery. Krüger's patient survived the operation for five days but then succumbed to pleurisy. Two other patients survived for fifteen and thirty-seven hours. In case of fat embolism, such as is liable to follow extensive fractures or crushing of the liver, it might be possible to expose the thoracic duct and divert its contents outward, as most of the fat is conveyed to the blood through the thoracic duct. In case of air embolism, especially when a vein is opened near the thorax, direct compression at once is the safest measure. The sound of the air entering the vein is never forgotten when once heard. A small amount of air is borne without harm, but when the blood in the right heart becomes foamy from admixture of air, the heart works in vain. As a last resort, the right ventricle might be punctured, to the right of the sternum, to release the air.

118. **Venesection and Gelatin in Treatment of Inflammation and Processes with Effusion.**—Luithlen has previously called attention to the modification in the test reaction of the skin after serum or colloidal substances have been injected. Recent research on serodiagnosis and serotherapy has confirmed his findings and also his assumption that the result has nothing to do with any property of the serum as an antigen but rather to the fact that the serum represents a colloidal substance and that it is to this colloidal property that it owes its efficiency in pregnancy dermatitis, etc. He has worked out a method of research to determine the permeability of the vessel walls under various conditions. About 100 c.c. of Ringer's fluid is injected into the abdominal cavity; half an hour later he injects into a vein in the ear 2 c.c. of a 10 per cent. solution of sodium ferrocyanid, and after intervals of one, two, three, four, six, eight and ten minutes, he withdraws a small amount of fluid from the abdominal cavity and examines it for the presence of the chemical. This series of tests is followed at once with a repetition of the procedure using 5 c.c. of a 2 per cent. solution of sodium iodid. The tests were made on rabbits, some of which had been previously treated with gelatin, some with colloidal silicic acid and some with serum, others with preceding venesection. The results show that there was marked delay in the passage of the intravenously injected chemical after the above preliminary procedures. On the other hand, the passage of the chemical into the abdominal cavity was notably accelerated when instead of the above, the animals had been treated beforehand with electrolytic substances or hydrochloric acid.

In short, the research reported demonstrates that parenteral administration of colloidal substances, albuminous or not, and repeated venesection materially reduce the permeability of the vessels in rabbits for chemicals introduced into the veins. These findings throw light on the benefit from Gilbert's autoserotherapy in pleurisy and peritonitis with effusion, and also on the benefit from repeated venesection in certain cases. They suggest that venesection deserves a prominent place in the treatment of various processes of an inflammatory nature with effusion, pneumonia, pleurisy, etc., as a reduction of the permeability of the vessels materially aids in recovery.

120. **Venous Thrombosis in Heart Disease.**—Glaser's patient was a young woman with mitral, aortic and tricuspid insufficiency who developed signs of obstruction of the superior vena cava. The right sternocleidomastoid muscle swelled first, then the parotid gland region on both sides, and the entire right side swelled enormously. Twenty-five cases of the kind are on record with necropsy in four; twenty-three of the patients were women, nearly all under 30. Chlorosis is probably a contributing factor.

126 Variations in Weight on Withdrawal of Carbohydrates. R. J. Carneiro.
127 Case of Congenital Stenosis of the Intestine. K. Stolte.

125. **Magnesium Sulphate in Spasmophilia.**—Berend used magnesium sulphate subcutaneously in treatment in forty cases, twenty-seven of spasmophilia and fifteen of eclamptic children without spasmophilia. Detailed case histories and clinical charts are given. His initial dose was 0.2 gm. in the form of 15 to 20 c.c. of an 8 per cent. solution. He tried using 15 and 25 per cent. solutions, but with no better effect. Twice this dose could be given daily to infants without any toxic effects. The quickest and most intense effect was on the electric excitability of the muscles and the spasms of the hands and feet. It acts somewhat more slowly on the general spasms and Trousseau's sign, and least of all on spasm of the glottis. Results were generally obtained in twenty-four hours, and it was seldom necessary to continue the treatment longer than four or six days. Phosphorus and cod liver oil were given in conjunction with it after the second day. The two treatments supplement each other. There are two marked advantages with this over other forms of treatment: recurrence seems to be much rarer and the course of the spasmophilia is decidedly shortened. Moreover, with this treatment mother's milk is less of an essential. There is no danger of inanition because food does not need to be withdrawn as in other forms of treat-

ment. The only point to be insisted on in diet is that it must be poor in salts. The *treatment is* also of value in convulsions not due to spasmophilia if there is no cerebral irritation or disturbance of kidney function.

140 Disease of the Pancreas. A. Stauder. Commenced in No. 41.

**129. Electric Exercise of the Abdominal Walls after Delivery.**—Brommer applies Bergoniés method to exercise the muscles, without the cooperation of the patient, to restore tone to the abdominal wall in the puerperium. The method induces rhythmical contraction of the muscles without pain. The woman sits in a reclining chair which has large electrodes in the back and seat. The other electrode is laid on the abdomen and pressed firmly against the skin by bags of sand. The procedure was applied the fifth day after delivery for fifteen minutes, increasing on later days to forty-five minutes, with the weight of the sand bags up to nearly 70 pounds. No inconveniences or pain were ever experienced, while it was his impression that the muscles of the abdominal wall and floor of the pelvis regained tone with unusual rapidity and completeness. Encouraged by these results, he applied the method to patients after laparotomies. His experience with it in cases of obesity has also been encouraging, but not much success in this line can be realized with a confirmed and continuous large eater. The method is also useful to prevent atrophy after fracture of a limb. He reiterates in conclusion that this electric exercising of the muscles in the maternity and postoperative cases had a surprisingly good effect on the *functioning* of the intestines. The bowels moved regularly one or two hours after the sitting in two-thirds of the thirty parturients, and this effect was also apparent in the laparotomy cases. The article gives an illustration of a patient taking the treatment.

**130. Treatment of Fracture of the Forearm with Supporting Rod.**—*Schöne* uses a rod of pure silver, from 2.8 to 4 mm. in diameter, slightly rounded at the ends. He trephines the bone *for* the introduction of the rod and works it in through the bone marrow to reinforce the arm; the silver has also antiseptic power. Two illustrations show the exact technic. He has applied the method in six cases and consolidation followed rapidly in five and more slowly in the sixth patient.

**132. Pathology of the Liver.**—Gundermann found that ulceration developed in the stomach or duodenum in guinea-pigs after the left branch of the portal vein had been ligated, thus cutting *off* three-fourths of the liver. The *clinical* picture that resulted, the findings *in* the *urine* and after death, were all typical of true uremia, although a uremia of liver origin seems paradoxic. These experiences suggested that perverted functioning of the liver may be the cause of uremia in man. A number of facts that have been recorded sustain the assumption of the dependence of kidney functioning on the liver. In further experiments he ligated the common bile duct and the resulting cholemia also presented the clinical picture of uremia except for the absence of convulsions. The clinical symptoms and the findings after death were so closely alike under all these circumstances that the same causal moment must be postulated for both. *It may* be wise to drop the term "uremia" for "hepato-renal intoxication," and call "cholemia," "hepato-cholic intoxication."

**134. Heart-Block Under Salvarsan.**—Fuchs' patient was in the *later* period of the secondary manifestations of syphilis, the heart findings normal. He was given up to 2.3 gm. salvarsan in the course of *nine* weeks. Forty-eight hours after *the last intravenous* injection of 0.6 gm. of salvarsan, actual heart-block developed, the pulse dropping from 80 *to 40; the* diagnosis of heart-block was *confirmed* by the electrocardiogram. Fuchs explains this occurrence as due to the destruction of a nest of spirochetes in the bundle of His by the fifth injection of salvarsan. The *endotoxins* liberated by this *destruction of spirochetes at this point* caused such disturbance *in the bundle* that the heart-block resulted. As the toxins were absorbed, conditions returned to *normal;* in seven days in this case.

**135. Primary Diphtheria of the Lung.**—David states that a boy of 9 was *taken* with what was apparently pneumonia of the left lower lobe terminating in a crisis and followed by slight pleurisy. The child was apparently doing well when *suddenly he seemed to be suffocating* but was relieved by inhalation of oxygen and epinephrin. A pneumonia process had developed in the right lower lobe and the bronchi and trachea *became obstructed so that an emergency tracheotomy* was required. *Diphtheric* membranes were expelled through the opening; antitoxin was injected but the child died the thirteenth day after his first symptoms. Diphtheria bacilli were found in the lungs and air passages in pure cultures.

146 Case of *Malignant Neuroblastoma of the Sympathetic Nerve.* N. Auitschkou.
147 *Histology of Nephritis Caused by Vinylamin.* Oka.

**141. Pathology of the Thymus.**—Hart finds that the thymus may persist and become enlarged but the *functioning may be* subnormal. The so-called status thymico-lymphaticus is due *not* to excessive thymus function but to a constitutional abnormality expressing itself in disturbances of the whole internal secretory system. The enlargement of the thymus is *only* one of its manifestations. The hyperplastic thymus seems to have a toxic effect *on* the heart. In many cases of exophthalmic goiter, enlargement of the thymus precedes the appearance of thyroid symptoms.

**143. Relation of the Thymus to Adrenal Secretion.**—*Adler* concludes from his research that the thymus secretion has the *effect of lowering the tonus* of the vascular system. Therefore, if the thymus secretion is increased, the *adrenal* secretion must also be increased to overcome this hypotonic *effect.*

The results showed *that* the coagulating power *of the blood* was very much reduced; there is evidently lacking some substance or substances, or they are inert for some reason, which are necessary *for coagulation.* The viscosity is also much reduced, as also the number of blood *platelets.*

### Zentralblatt für Chirurgie, Leipsic

*October 25, XL, No. 43, pp. 1657-1704*

153 *Tetany with Abdominal Disease a Bad Sign. E. Bircher.
154 *Acute Congestion of the Liver from Acute Cardiac Insufficiency. (Ueber perakute Leberschwellung.) M. v. Brunn.

153. **Tetany with Peritonitis.**—Bircher has made a special study of symptoms suggesting tetany among 537 patients with various stomach and intestinal affections. They were noted in twenty-eight cases, and twenty-two of these patients died; all had peritonitis from perforation of a gastric or duodenal ulcer or appendix or from ileus, except in one case of fatal postoperative dilatation of the stomach and three fatal cases of peritonitis from other causes. No symptoms suggesting tetany were noted in twenty-five cases of simple gastric ulcer, nor in eighty-five of gastric cancer or hundreds of cases of simple appendicitis. The conclusion seems evident that absorption of toxins from a badly diseased peritoneum is responsible for the tendency to tetany, and consequently signs of it render the prognosis grave, especially tonic twitching in the arms and legs, the Chvostek facialis sign and the Trousseau sign. In a number of the cases it proved possible also to elicit the Schlesinger leg sign.

154. **Acute Congestion of the Liver.**—Von Brunn reports a case similar to the three recently published by Ortner and summarized in these columns November 1, p. 1670. Brunn's patient was a young man suddenly taken with abdominal pain increasing to extremely severe collapse in twenty-four hours. Examination then showed the heart with normal outlines, sounds pure, pulse 22 with irregular intervals, the abdomen retracted, the upper portion tender and stiffening at any attempt at palpation, the lower portion not tender, moderate dulness over the right upper abdomen, extending to below the umbilicus. The diagnosis veered toward perforation of the stomach, but the exploratory laparotomy disclosed no signs of inflammation and only a much enlarged liver and an enlarged and tough spleen. Relief was almost immediate after the exploratory operation, and the young man was soon completely restored. Eleven days later the heart was found extending a finger-breadth beyond the left nipple line and a systolic murmur varying in intensity was audible over the entire heart. This murmur was still perceptible nine days later, but the liver was apparently entirely normal. He explains the acute congestion in the liver in the same way as Ortner, Nature driving the blood into the liver in case of acute insufficiency of the heart, thus giving the heart a chance to recuperate as by a venesection.

158 *Treatment of Pyelitis by Lavage of the Renal Pelvis. (Sulla cura delle pieliti col cateterismo ureterale e lavaggio del bacinetto renale.) F. Cuturi.

158. **Local Treatment of Pyelitis.**—Cuturi insists that direct medication of the kidney pelvis through the ureter catheter is absolutely indispensable in all cases of pyelitis except those of tuberculous or concrement origin. He flushes out the pelvis in this way every day and instills a 1, 2, or 4 per cent. solution of silver nitrate not oftener than once in three or four days, as a rule, washing it out well afterward. In a case of bilharzia pyelitis reported he injected 5 c.c. of a 1 per cent. solution, rinsing it out after a few minutes. The pain was relieved at once. The procedure was repeated ten times on alternate days, gradually increasing the strength to 3 per cent., and a few supplementary times at week or fortnight intervals later. The patient was soon clinically cured. Eight applications conquered the pyelitis in a gonococcus case described and five in a colon-bacillus case of puerperal pyelitis.

159 *Hereditary Ataxia in Pellagrin Family. L. M. Ruggieri.
160 Medical Fees in Ancient Times. (Gli onorari dei medici nell'antichita.) P. Picca.

159. **Friedreich's Disease in Brother and Sister.**—The first symptoms of the ataxic paraplegia developed at about the age of 12 in the brother and sister whose cases are reported. The patients are now 27 and 16. The young man had malaria of the tertian type as a youth, and all the members of the family show more or less signs of pellagra. Ruggieri discusses whether the pellagra may have been responsible for the disease. The type of paraplegia and ataxia seems to be identical in both. The disturbance in gait developed gradually, fully two years elapsing before the ataxia was well defined. The illustrations show the typical deformity of the feet.

165 *Diphtheria. J. L. Labberté and L. Talsma.
166 *Congenital, Familial Edema of the Legs. J. C. van Vliet.

161. **Poison or Diabetes?**—Pel discusses a recent medicolegal case to emphasize the necessity for a body of qualified medical experts appointed by the state to pass on all the forensic questions in cases like the one described. A man of 41 died with symptoms of diabetic coma. Weeks later, 0.0256 gm. of morphin was found in the exhumed body. Only the chemical diagnosis had weight with the court at the trial of the person suspected of having poisoned the deceased. All the clinical symptoms of the diabetic coma were systematically ignored in the evidence although they had been very prominent, in contrast to the symptoms from the morphin.

163. **Improved Technic for the Wassermann Test.**—Kapsenberg advises the use of the water-bath instead of incubating the test-tubes for the Wassermann test. This materially shortens the time required for the test. Half an hour is sufficient to read the results when the water-bath is used. The test-tubes are affected by the temperature of the water much sooner than in an incubator, and he states that the findings are more reliable. He says further that it is often difficult to procure fresh material for the antigen and, as usually prepared, it is not durable. These drawbacks can be avoided by using human heart tissue for the purpose, prepared in the form of a dry powder which is always ready for use and seems to keep perfectly. The antigen prepared from the heart powder according to his method is not hemolytic and does not inhibit the hemolysis from the complement. He never witnessed pronounced inhibition of hemolysis with a non-syphilitic serum.

164. **Traumatic Neurosis.**—The accident to the foot bringing on the neurosis occurred while the letter carrier was on duty. De Haan discusses in connection with this case the various phases of workmen's compensation and accident insurance. He warns that the indemnity should not be large in such cases, as the patient must learn to be self-reliant and not give up to chronic invalidism and thus exert a bad influence on subsequent cases of the kind. The amount of earning capacity left for the same or another occupation is also an important factor in estimating the compensation to be allowed.

165. **Diphtheria.**—There were 130 cases of diphtheria in the last two years at Krommenie, with a population of only 4,000. A careful epidemiologic study of all the cases is here summarized. There was paralysis of the heart in 34 cases and seven in this group died; 15 cases of paralysis of the soft palate;

4 of accommodation, and 1 of the internal rectus muscle; 3 of the back and 1 of the calf muscles, but the paralysis did not prove permanent in any instance. On account of the apparent mildness of the epidemic, antitoxin was applied in only 42 cases and 20 of these children had paralysis in some form; in 4 the paralysis of the heart proved fatal. Of the 88 children not given antitoxin, 3 died of cardiac paralysis of the 11 who had paralysis in some form. Of the 12 given antitoxin the first day, 6 developed paralysis and 1 died. Of the 17 receiving the antitoxin the second day, 8 developed paralysis and 2 died of cardiac paralysis. Of the 13 children who were given antitoxin at a still later date, 6 developed paralysis and 1 died from heart failure and 1 from the severity of the diphtheria. The paralysis seemed to occur in waves during the epidemic, some periods furnishing far more cases than others. Ninety-five bacillus carriers were found among 1,378 children tested for the bacilli. The carrier children were dismissed from school but no instance of infection from them is known. The epidemic, however, died out when the schools were closed. A number of the throat smears were negative at several examinations but later gave positive findings.

166. **Familial Edema of the Legs.**—Van Vliet gives the chart of a family in which congenital edema of the legs occurred in thirteen members in four generations, ten males and three females. In the six clinical cases no cause for the familial edema could be discovered.

*October 22, No. 43, pp. 1261-1292*

173 *Polypous Gastritis. E. Meulengracht.

171. **Impressions of America.**—Rovsing depicts in flattering terms his impressions during his recent trip to America. He compares the various surgical centers he visited and the technic of the surgeons, and remarks that the tendency to copy after European technics and models is a distinct hindrance to the development of an independent surgery in America. He adds that American surgeons believe so implicitly in the supremacy of European surgeons that the result is a certain lack of confidence in themselves.

173. **Polypous Gastritis.**—The findings are illustrated of the gastritis with production of polyps discovered at necropsy of a woman of 66 and a man of 82. It had caused slight or no clinical symptoms. There was no sign of cancerous degeneration. Complicating malignant disease is known in only four of the twenty-four cases on record of polypous gastritis.

174 *Treatment of Empyema of the Pleura by Tapping and Inject- [illegible] and Glycerin. G. Nyström.

175 * [illegible] from Chilling. O. Lindbom.

176 *Syphilis of the Lung. [illegible] Lindvall and J. Tillgren.

174. **Empyema of the Pleura.**—Nyström reports in full fourteen cases of pleural empyema treated by tapping and injection of formaldehyd in glycerin. The results were not encouraging, and he says this method should by no means take rank with thoracotomy. Helling has been more successful with it, and Maldarescu reported in 1910 good effect from repeated injection of 10 to 12 c.c. of a 10 per cent. alcohol solution of alphanaphthol in seven cases of empyema.

175. **Hemoglobinuria from Chilling.**—Lindbom reports the minute details of a typical case of paroxysmal hemoglobinuria. The patient was a sailor of 46 and the attacks could be brought on by holding the hands in ice-water for fifteen minutes. The Wassermann test was positive. Some benefit was derived from cholesterin given in six intramuscular injections in the dose of 0.5 gm. cholesterin, in a 10 per cent. suspension in physiologic salt solution. The Wassermann reaction became negative after this, and the test chilling of the hands induced only a rudimentary attack of hemoglobinuria, and there was no further attack until forty days after the close of the treatment. Cholesterin was given later in an oil emulsion by the mouth, but it did not display any efficacy by this route as a typical attack followed next day on the test chilling of the hands. As cholesterin checks the Donath-Landsteiner reaction in the test-tube, Lindbom suggests that the autolysin involved in this reaction and the substances giving the Wassermann reaction may be identical.

176. **Pulmonary Syphilis.**—In the two cases described the findings in the lungs were not actually specific for syphilis, but the changes in the lungs were accompanied by adjacent lesions of unmistakable syphilitic nature, and the arteries also showed signs of syphilitic injury. The first case is interpreted as a true syphilitic affection of the lung; the second case as merely a patch of hepatization in the lung of a syphilitic. The first patient had no history of tuberculosis; the present lung affection had run its course in less than a year; there were no consonant râles and the sputum was merely catarrhal.

179 The Virus of Fowl Leukemia. (Undersøgelser over Hønseleukaemiens Virus.) V. Ellermann.

180 Appendicitis in Femoral Hernia; Two Cases. H. Kaarsberg.

177. **Combined Arhythmias.**—Petersen reports four cases of a combination of various forms of arhythmia. In the first a man of 65 had complete heart-block associated with pulsus alternans. In the second case, the complete heart-block was associated with auricular flutter. In the third, the Adams-Stokes syndrome developed probably as a manifestation of poisoning from digitalis. Poisoning from digitalis was also probable in the fourth case in which auricular flutter was accompanied by coupled beats (bigeminia cordis). The appearance of coupled beats warns to suspend the digitalis, as a rule, but in the case described conditions grew so much worse on suspension of the digitalis for a few days that it was resumed again. The various curves of these cases are compared and the necessity for close supervision of patients taking digitalis is emphasized anew. The signs of intoxication may develop suddenly, even before the full therapeutic action has been manifested. Pulsus alternans is easily overlooked, he remarks, but it can generally be diagnosed by applying the cuff to the upper arm. Treatment is mainly by bed rest and a diet to spare the heart. Digitalis is not required unless for severe symptoms of insufficiency, and then only with great caution; it may correct the pulse in some cases but there is no doubt that pulsus alternans may develop as a result of digitalis poisoning. Auricular flutter with complete heart-block is not corrected by digitalis; the auricular flutter persists unmodified as a rule.

178. **Inherited Hemeralopia.**—Heerfordt explains night blindness and day blindness as the result in the majority of cases of a torpid condition of the retina, which in turn is the result of a general influence on the functioning of the retina from a defective nutritional condition. This so-called idiopathic form is important in general practice as the disturbance is so typical and as it is by no means rare, while it responds so promptly and effectually when the diet is changed to include proper amounts of fat and egg albumin. He urges practitioners to be on the lookout for it in children.

# SHOCK *

GEORGE W. CRILE, M.D.
Professor of Surgery, School of Medicine, Western Reserve University
CLEVELAND

The theory of shock so ably advocated by my gifted friend Professor Henderson and my theory may in many important respects be harmonized. It seems best, however, to leave that to the future and to proceed at once to the presentation of the summaries of a long series of experiments and clinical observations in support of the kinetic theory which I have proposed elsewhere. This theory is called the kinetic theory because it is based on the phenomena and the consequences of the transformation of latent energy into kinetic energy as an adaptive response to environmental stimuli.

In this paper, therefore, I shall discuss the pathology of traumatic shock; of emotional shock; of toxic and foreign proteid shock; and of drug shock. These several forms of shock will be considered in their acute and in their chronic stages and certain probable relations will be indicated between the several forms of shock and certain diseases, such as indigestion, neurasthenia, glycosuria, Graves' disease, cardiovascular disease and nephritis.

Let me at once state my principal conclusion—that all forms of shock are caused by overstimulation and consequent exhaustion; that the brain-cells show physical changes corresponding to each stage of the cycle of shock, and that with each shock-producing agency which I have studied there is shown in the brain-cells a hyperchromatic stage followed by a hypochromatic stage.

The organs of the body especially involved in shock are certain organs whose function is that of converting latent energy into kinetic energy in response to adaptive stimulation. These organs—among which are the brain, the thyroid, the adrenals, and the muscles—I have called the kinetic system because of this peculiarly kinetic function. In response to environmental stimuli of any sort these organs convert latent energy into motion or into heat. In this thesis, however, I shall consider only the conversion of latent energy into motion as a response to the need of self-preservation against physical injury or infection.

As evidence, will be presented clinical and experimental observations of the energy-producing results of physical injury alone; of physical injury under inhalation anesthesia; of the emotional stimulation of fear alone; and of foreign proteid and toxic stimulation alone; and their results will be considered in their relation to the brain, the adrenals and the thyroid.

## TRAUMATIC SHOCK

A working histologic standard for the brain was established and compared in a large number of brains with the immediate and later effects of physical injury under inhalation anesthesia in an intact animal and in a spinal dog; of physical injury in dogs with crossed circulation; and of physical injury, within the territory of anesthesia, in dogs under local anesthesia; of injections of toxins; of injections of strychnin and morphin; of various inhalation anesthetics; of severe hemorrhage and of fatigue from both physical exertion and prolonged wakefulness.

In case of physical injury alone inflicted on normal dogs under anesthesia, in the brain-cells was found first a stage of hyperactivity characterized by hyperchromatism; and later a stage of exhaustion characterized by chromatolysis, by alteration of nucleocytoplasmic relation, by rupture of the nuclear and the cell membrane and, finally, by disintegration. These changes were most marked in the cortex and the cerebellum, less marked in the medulla and in the cord.

The brain-cells showed no change when the trauma was limited to territories disconnected from the brain by severing the spinal cord, or by local anesthetization. When the circulations of two dogs were crossed and but one dog was traumatized, brain-cell changes were found only in the dog traumatized. Dogs overtransfused and traumatized showed brain-cell changes. Under nitrous oxid the brain-cell changes after equal trauma caused about one-third as much change as under ether. When the vitality was previously reduced by emotion, by physical exertion, by toxins, by infection, by hemorrhage, by excessive thyroid feeding, by adrenalectomy—or by any cause that reduces the vital power — greater changes were found after equal trauma, the endurance of the animal being in proportion to its vitality at the beginning of the experiment.

Testing the effects of shock-producing traumatism on the output of epinephrin by Cannon's method I found no increased epinephrin output resulting from trauma under anesthesia. In addition there were no gross changes observed in the thyroid in either the laboratory or the clinic as a result of shock-producing trauma.

From these observations I conclude that ether anesthesia offers no protection to the brain-cells from the effect of trauma; and that the lipoid-solvent anesthetics break the arc causing consciousness beyond the brain-cells somewhere in the efferent path; hence the afferent stimuli reach and modify the brain-cells as readily as if no anesthetic had been given. I conclude therefore that the brain-cell changes are due to the discharge of energy in a futile effort to escape from the injury.

---

* Paper read before the Seventeenth International Congress of Medicine, London, England, August 6-12, 1913.

### EMOTIONAL SHOCK

In rabbits subjected to the emotional stimulus of fear alone the brain-cells showed precisely the same changes as those which resulted from physical injury, namely, an immediate stage of hyperchromatism and a later stage of chromatolysis: a disturbance of the nucleoplasmic relation and the final disintegration of many cells.

As a result of strong fear repeated daily for two weeks as many as 18 per cent. of the Purkinje cells were actually destroyed, and many animals died. In cats the emotion of rage caused a striking increase in the output of epinephrin, but in cats subjected to fear and rage a month after division of the major and the minor splanchnic nerves, there was no increase in the output of epinephrin. In rabbits acute fear caused a rise in temperature of from 1 to 3 degrees, excepting in thyroidectomized animals whose temperature remained subnormal. In rabbits nephritis often resulted from repeated fright.

### TOXIC AND FOREIGN PROTEID SHOCK, ANAPHYLACTIC SHOCK

To determine the histologic changes produced by toxic and foreign proteid shock, and by anaphylactic shock, the brains of many human beings who had died of infections and of eclampsia were examined, and in the laboratory were studied the brains of many animals in which there had been injected toxins of streptococci, staphylococci, colon bacilli, gonococci and tetanus bacilli; the brains of animals to which there had been given intravenously peptones, leucin, skatol, extract of feces, alien blood-serum; of animals in anaphylactic shock; of animals in which placental extract had been injected. In all instances observations were made as to the effect of the injections on the epinephrin output, and the brain-cell changes. In every instance the brain-cells showed precisely the same changes as were seen under traumatic injury, and emotional injury—first a stage of hyperchromatism, followed by a stage of chromatolysis and cell disintegration. Of special interest was the fact that these various toxins and foreign proteids, as well as anaphylaxis and placental extract, produced a large increase in epinephrin output. But if the nerve-supply of the adrenals had been first divided, then these agents caused no increased output of epinephrin; or if deep morphin narcotization had been first induced there was no increased epinephrin output in toxic and anaphylactic shock.

### DRUGS—ANESTHETIC, NARCOTIC AND STIMULANT

Many observations of the brain-cells and the epinephrin output were made after the administration of ether, urethane, nitrous oxid and morphin. None of these caused either brain-cell changes or increased epinephrin output.

Here again it was of special significance to note that, under heavy morphin dosage, there was no increased output of epinephrin as a result of anaphylactic shock. It was found also that the normal output of epinephrin was diminished by morphin. Strychnin, on the other hand, caused brain-cell changes of precisely the same type as did the emotions, toxins, and foreign proteins, that is, at first hyperchromatism and later chromatolysis; and there was also increased epinephrin output. Previous division of the adrenal nerve-supply prevented the increased output of epinephrin.

These experimental results may be summarized as follows: All the factors that cause the activation of the kinetic system, whether emotional, toxic, foreign protein, or drug, produce identical brain-cell changes and increased epinephrin output. On the other hand, the anesthetics and the narcotics cause neither brain-cell changes nor increased epinephrin output, while strychnin causes both. Clinically, it is known that those agencies that in my experiments were proved to cause an increased activity of the brain and the adrenals, also aggravate cases of Graves' disease. It is known also that in those cases of Graves' disease in which changes in the size of the thyroid may be noted, increase in its size is seen as a result of emotional excitation; of infections; of toxemia, and of intense physical and mental work. There is strong clinical evidence, therefore, of the activation of the thyroid by the same influences that activate the brain and the adrenals.

I have shown that in traumatic shock, emotional shock, foreign protein shock, and strychnin shock, identical physical changes in the brain-cells are found. Excepting in traumatic shock under inhalation anesthesia the adrenal glands are activated by the same agencies that cause work changes in the brain. Clinically it is known that the same influences cause thyroid activation.

I conclude, therefore, that shock is a work-exhaustion phenomenon; that the brain, the adrenals, the thyroid and the muscles have but one way of responding to stimuli; and that the conversion of energy is through the activity of these kinetic organs. What work is done in response to foreign protein stimulation? Through the heat-producing activity of the kinetic system foreign proteins such as bacteria are destroyed. Since heat interferes with the growth of bacteria, I must believe that fever is an adaptive reaction to the presence of bacteria in the body and that it is produced by the conversion of latent energy into heat through the same mechanism that converts latent energy into motion. Hence after stimulation by foreign proteins with resultant fever the work changes seen in the brain, the thyroid, the adrenals, and in all parts of the kinetic system are the same as the work changes seen after the conversion of energy into motion.

Shock, then, is the result of an intense stimulation of the kinetic system which leads to physical changes in the kinetic system and which if carried far enough exhausts the system and even destroys some brain-cells. The kinetic system is constantly activated so long as there is life, but normal activation does not produce exhaustion. If normal activity of the kinetic system be exemplified by walking, shock might be exemplified by the exhaustion caused by a Marathon race. The differences between normal processes and shock is that of intensity, not of kind. From these premises it becomes obvious that the exclusion of both traumatic and emotional stimuli will wholly prevent the shock of surgical operations.

When the kinetic system is continuously or intermittently overstimulated through a considerable period of time, so long as all the links in the kinetic chain take the strain equally, the result will be excessive energy conversion, excessive work done. Usually under stress, however, some one link in the chain will be unable to take the strain and then the evenly balanced work of the several organs of the kinetic system is disturbed. If the brain does not take the strain, then neurasthenia, nerve exhaustion, or even insanity, will follow. If the thyroid is not able fully to take the strain, it undergoes hyperplasia, which in turn may result in a colloid goiter or in exophthalmic goiter. If the adrenal does not take the strain, there may be developed cardiovascular disease or glycosuria.

From the foregoing one is able to understand the muscular weakness following fever; one can understand why the senile have neither muscular power nor strong febrile reaction; why long-continued infections produce pathologic changes in the organs constituting the kinetic chain; why the same pathologic changes result from various forms of activations of the kinetic system. In this hypothesis we find a reason why cardiovascular disease may be caused by chronic infection, by autointoxication, by overwork, or by emotional excitation. We see now that the reason why we find so much difficulty in differentiating the numerous acute infections from each other is that they play on the same kinetic chain. Our postulate harmonizes the pathologic democracy of the kinetic organs, for it explains not only why in many diseases the pathologic changes in these organs are identical, but why the same changes are seen as the result of emotional strain and overwork. It can thus be understood how either emotional strain or acute or chronic infections may cause either exophthalmic goiter or cardiovascular disease; how chronic intestinal stasis with the resultant absorption of toxins may cause cardiovascular disease, neurasthenia, or goiter. Here is found an explanation of the phenomena of shock, whether the shock be the result of traumatic or psychic stimuli, or of a surgical operation with its combination of both psychic and traumatic elements.

This conception of the kinetic system has stood a crucial clinical test by making possible the shockless surgical operation. It has offered a plausible explanation of the cause and the treatment of Graves' disease. Will this kinetic theory stand also the clinical test of controlling that protean disease bred in the midst of the stress of our present-day life? Present-day life in which one must ever have one hand on the sword and the other on the throttle, is a constant stimulus of the kinetic system. The force of these kinetic stimuli may be lessened at the cerebral link by intelligent control; a protective control is empirically attained by many of the most successful men. It may be broken at the thyroid link by dividing the nerve-supply, reducing the blood-supply, or by partial excision; or if the adrenals feel the strain, the stimulating force may be broken by dividing their nerve-supply. No theory is worth more than its yield in practice, but the straw of clinical evidence from a single case points toward a new method of control of cardiovascular disease. I have proved that animals remain in apparently good health after the division of their adrenal nerve-supply, and in one human patient with cardiovascular disease in whom the adrenal nerve-supply was divided the blood-pressure gradually fell and remained at a lower level than prior to the operation. The patient is in good condition. As it stands alone, however, this case proves nothing.

### SUMMARY

There is a group of organs whose function is the conversion of potential into kinetic energy. These organs form a kinetic system. Among the organs forming this system are the brain, the thyroid, the adrenals, and the muscles. The kinetic system converts latent energy into motion or heat in response to adequate stimuli. If the stimuli are overwhelmingly intense, then the kinetic system—especially the brain—is exhausted, even permanently injured. This condition is acute shock. If the stimuli extend over a period of time and are not so intense as to cause an immediate breakdown or acute shock, their repetition may cause the gradual exhaustion of the kinetic system—this condition may be called chronic shock. Either acute or chronic shock may be measurably controlled by weakening or breaking the kinetic chain at any point. This has already given us the shockless operation and it opens a possibility of controlling certain chronic diseases of that intensely kinetic organism, civilized man.

# THE RÔLE OF THE TENDO ACHILLIS IN THE ETIOLOGY OF WEAK-FOOT *

EMIL S. GEIST, M.D.
Instructor of Orthopedic Surgery, University of Minnesota, Medical Department
MINNEAPOLIS

It is a modern conception that weak-foot, or flat-foot, (insufficientia pedis—Schanz) is primarily caused by a loss of balance of the muscles of the leg and foot; that the interference with the proper function of these various groups of muscles which is caused by abuse, disuse, injury or disease, will be followed by weakness of one or more of these muscular groups; that from this there results a disturbed relationship of function between the various individual muscles of the leg, and, finally impairment of the carrying power of the foot.

Huebscher[1] has shown that the group of muscles forming the Achilles tendon (gastrocnemius, soleus and plantaris), has the same volume as all the remaining muscles of the leg combined and probably for that reason has approximately the same relative strength. It is not to be wondered at that interference with the proper function of this powerful group of muscles, caused by shortening, would interfere materially with the proper use of the foot.

While the relationship of the short Achilles tendon to weak-foot has been written of from time to time, sometimes very fully, sometimes in cursory fashion, there are still a great many able articles which treat of the subject of weak-foot, yet which devote no time to this etiologic factor.[2] That a short Achilles tendon often accompanies a rigid weak-foot is well known.[3] In fact, a part of the proper treatment of such a rigid weak-foot consists either in division or in the lengthening of this large tendon.

The fact that a shortened Achilles tendon is a causative factor in many cases of beginning weak-foot is not of new observation. Schaffer[4] of New York was the first in this country to call attention to this. His article on the subject is worth reading in full. Shortly before publishing this paper, Schaffer made the statement, perhaps a little too comprehensive, that nearly every case of flat-foot which he sees presents a shortened tendo Achillis.

---

[4] Schaffer, Newton M.: Flat Foot, Its Causes and Treatment, New York Med. Jour., 1897, lxv, 717.

Soon after the publication of Schaffer's paper, there appeared, in the literature, sporadic references to this subject; some authors laying stress on the relationship that exists between the two conditions. Bradford and Lovett[5] distinctively mention this in their text-book as a cause for weak-foot.

The cause of the shortening of the heel cord is often not far to seek when we remember the high-heeled shoes that women wear. Hoffman[6] says: "The high heel, especially the one placed well forward, compels the wearer to stand largely on the front of the foot, which must bear more than its proportionate share of the body weight. The habitual wearing of the high-heeled shoes leads to shortening of the calf muscles through accommodation to the continually assumed attitude. This is probably the reason that a large percentage of middle-aged women *cannot dorsiflex the foot to quite* a right angle without relaxing the calf muscles by bending the knee."

In my own experience I have seen many cases of beginning weak-foot in adolescents who have never worn a high-heeled shoe. For the cause of the shortened heel cord in these cases, I have no explanation. Blodgett[2] and Williams[7] came to almost identical conclusions in two interesting statistical studies regarding the relative frequency with which a shortened tendo Achillis occurs in patients complaining of weak-foot. Neither, however, seems to have considered the possible etiologic relationship of the shortened heel cord to the symptoms. Blodgett, in an examination of 1,000 patients, finds evidence of shortened heel cord in 175 cases, or 17.5 per cent. Williams finds a shortened Achilles tendon in 65 out of 300 cases, or 18.3 per cent. The great majority of Williams' patients with shortened Achilles tendon were women and Williams blames high heels for this condition.

Abbott and Pingree[8] have done some interesting experimental work on the normal balance of the foot. Among other things, they have shown (Experiment 1), that when the heel cord is shortened artificially in a dissected weak-foot, it is impossible to raise the arch to the normal position by traction on the anterior and posterior muscles; but, if the tendo Achillis is divided, that the inner border of the foot can then be easily raised to the desired height. In other words, the tibialis anticus and posticus are working under disadvantageous conditions when the heel cord is short.

Before I knew of the existence of Schaffer's classic work, I was able to demonstrate to myself in a few dissections of the foot that when the heel cord was shortened artificially so that dorsiflexion was impeded, a little more movement of the anterior portion of the foot was made possible by vicarious movement in the mediotarsal joint; this movement being in the sense, not only of dorsiflexion, but also of pronation.

Then I understood why it was that a patient with a shortened heel cord was able to bring the foot a little more toward a right angle when the foot was slightly abducted. In practice, I have found that some of my most obstinate cases of weak-foot present the condition of a shortened heel cord. For the last two years, I have not hesitated to advise section of the tendo Achillis in these cases preparatory to the usual well-accepted forms of treatment of weak-foot, believing that, when present, the shortened heel cord stood in etiologic relationship to the symptoms.

I now have fifteen cases in which the time since operation exceeds one year. All of these patients are walking much better than they did before the operation. From what I can learn, every one is satisfied and pleased with the results of the operation. I have always divided the tendo Achillis subcutaneously, usually cutting it obliquely; occasionally dividing it according to the method of Bayer. One case-report may serve as an example of all of them:

Case 1.—Miss R., aged 38, a housekeeper, stands much of the time, wore high-heeled shoes years ago and comes with typical symptoms of weak-foot. There is pain on arising from bed, also aching feet and inability to walk any distance without discomfort. She has tried all kinds of braces and shoes. Braces and shoes applied by myself gave only moderate relief. Achillotomy advised and done January, 1911. A plaster cast was used for six weeks. Following the removal of the cast there was considerable swelling of the feet for some time, so that the patient became very much worried about it. Properly graded exercises were begun and proper shoes and mechanical supports were adjusted. Two years later, the patient can walk as far as she wants to and has no soreness excepting a little after a hard day's work. The patient is much pleased with the result.

During the last six months I have been operating on these patients under gas anesthesia, thereby eliminating the only possible danger which attended this operation before, namely, that of complications due to ether.

Dr. Schaffer describes in his article an apparatus for slowly stretching the tendo Achillis. Perhaps I should have tried this method before resorting to operative procedures. As the element of time, however, is important to most of these patients, it is my opinion that section of the tendo Achillis probably will always be the quicker method of achieving the desired result, namely, that of lengthening this tendon.

One word further as to the examination of patients: In testing for a shortened heel cord, we must be sure to have the patient's knee straight, for the obvious reason that the insertion of the gastrocnemius is above the knee-joint. With the knee bent, there is a great deal of slack, which is taken up when the knee is extended as in standing.

### CONCLUSIONS

1. Shortened tendo Achillis accompanies at least 16 to 18 per cent. of all cases of beginning weak-foot.
2. There is experimental evidence at hand, easily to be reproduced, that a shortened heel cord can alter the range of motion of the foot and cause eversion to accompany continued dorsiflexion.
3. By simple division of the heel cord, we restore to the foot a certain range of normal motion, which has become lost to it, and without which normal range of motion the foot cannot properly perform its varied functions.

### ABSTRACT OF DISCUSSION

Dr. Charles A. Parker, Chicago: I have not had any experience with the method of treatment mentioned by Dr. Geist, but I wish to speak with regard to the possible action and reaction after the tendo Achillis is cut. It is the only extensor of the arch of the foot behind the ankle. All the structures in the sole are flexors of the arch; and when it is cut, they have a tendency, I suppose, to produce a type of calcaneum that, of course, does not go on to complete development; but it allows the structures in the sole of the foot to develop an arch.

**DR. ROLAND MEISENBACH**, Buffalo, N. Y.: Dr. Geist's paper is very important, from the fact that many cases of weak feet due to the tense calf muscle are overlooked. The paper recalls to my mind two cases which yielded stubbornly, one in a strong, healthy woman who had weak feet and beginning flatfoot, in which I am sure that the prime factor of discomfort was the shortening of the tendo Achillis. Temporary relief was given by stretching the calf muscles. In the other case I tried every means to relieve the condition except section of the tendo Achillis, which was refused by the patient. I think that it is much better to do the open operation in lengthening the tendon rather than to section subcutaneously, especially in adult patients with large tendons, as thereby one is less liable to produce a large callus which may delay convalescence.

**DR. FREDERICK C. TEST**, Chicago: I cannot quite agree with Dr. Geist in calling this condition a true case of weak-foot. It seems to me that weak-foot is due to relaxation of the muscles and ligaments; and that in this condition it is rigidity and shortening of the tendo Achillis, and often of the peronei tendons as well, that is the cause of the trouble. It is more a contraction than a relaxation. I have seen many patients who objected to section of the tendo Achillis, and in these cases I have obtained good results by removing the heel and thickening the sole, so as to lift the front of the foot, and then after a few weeks stretch the shortened heel tendon, thus solving the same mechanical problem along bloodless lines.

Instead of calling such a deformity "weak-foot," I call it the "high-heel hobble."

**DR. NEWTON M. SHAFFER**, New York: This question of the effect of a shortened tendo Achillis on flatfoot is, I think, one that I was the first to bring before the profession. I stated at one time that every case of flatfoot had a shortened heel-cord. I wish to reiterate that statement to-day with a slight modification. It all depends on the way the foot is examined, whether it can be demonstrated or not. The foot, as you know, is abducted in simple flatfoot—not the inflammatory kind—which is the last stage of the condition. If you take the patella as your guide and bring the tarsus immediately under the patellar line and then attempt to get flexion of the ankle-joint, dorsal flexion will stop inside a right angle. Underlying all these conditions may be lack of nutrition.

With a long tendo Achillis and tight plantars, you have a hollow foot, while with a short tendo Achillis and flabby plantars, you have a flatfoot. I have seen the conditions pass from one type to the other. A girl with a hollow foot weakened with ordinary illness will have so much strain thrown on it that the plantar fascia gradually yields and produces flatfoot. I wish therefore to reiterate what I have said before, and still believe to be the truth, that in 90 per cent. of the cases of flatfoot I can demonstrate a short tendo Achillis.

I have come to believe that division of the tendo Achillis is the best method of treating the more advanced and resistant cases.

**DR. EMIL S. GEIST**, Minneapolis: I have not yet encountered a case of excessive callus that gave trouble; hence, since subcutaneous division has been so satisfactory up to date I shall continue with it. We are all, no doubt, familiar with the small epidemics that we see every summer, when the young ladies discard high-heeled shoes and play tennis and other athletic games that bring them down on their heels and require them to put a pull on the tendo Achillis with bad results at times.

I wish to reiterate the statement that this is only one stage. It is necessary to follow up the operation of achillotenotomy with the measures that, in the years gone by, we have already learned to appreciate, namely, proper shoes, braces and exercises.

Regarding the priority of Dr. Schaffer, I would say that the only authority that I have for not mentioning the doctor as being the first to point out the relationship of short heel-cord to weak foot, is Hoffa, who mentions in this connection the name of Krauss. I have been unable to locate the work of Krauss on this subject.

# CERTIFIED MILK *

THOMAS C. McCLEAVE, M.D.
BERKELEY, CAL.

The propaganda for clean milk has been one of the chief factors in the development of the "Social Welfare" movement during late years. In all our centers of population certified milk is an important item in the food supply of the baby and its production engages the attention of many of our best sanitarians and pediatrists.

We find that there is still prevalent in the profession, even where we would least expect it, much misconception as to what certified milk is and what benefit is to be expected from its use. Thus we often hear certified milk spoken of as if it were identical with pasteurized milk, and I have known physicians to advise against the former on the ground that to heat milk made it unfit for infant-feeding, although certified milk is, of course, not heated at all. In THE JOURNAL of the American Medical Association we find the question asked, "Is Certified Milk Safe?"[1] and the emphasis is there laid on the dangers which are inherent in all milks and against which even certified milk cannot absolutely guard. In the *American Journal of Diseases of Children* we find quoted[2] without unfavorable criticism a standard of 30,000 bacteria per cubic centimeter; while in a paper[3] read before this Section last year it is asserted that a "waste of money and effort accompanied the work of many of the charities which confined their efforts to the distribution of clean milk, of which so much was once expected, but which accomplished little more than to help to prove that impure milk plays by no means the most important part in the causation of infant mortality." What the writer of the article doubtless had in mind was the now generally recognized truth that impure milk is but one of the many factors in our tremendous infant morbidity and mortality, and that measures for the prevention of summer diarrhea and similar diseases, which are predicated only on the furnishing of clean milk for children's use, have not been so successful as at first was anticipated; but that these efforts were barren of results as affirmed by the writer of the criticism, is absurd. All agencies intended to improve the living conditions of the children of our poor take their origin from the pure milk movement, and have, as one of their most important functions, the proper feeding of the babies under their control. This means, as a primal necessity, that the milk furnished them shall be clean.

Because of lack of information on this subject among the profession at large, and because of the recent adoption by the American Association of Milk Commissions of a code of requirements which it is hoped will eliminate discrepancies in the requirements of different commissions and which will make the production of certified milk uniform throughout the country, it has seemed to the officers of the association that this was an opportune time to bring to notice the provisions of this code and to make more accurate the general conception as to what certified milk is.

The certified milk movement originated with Dr. Henry L. Coit,[4] who, after several years' ineffectual effort to improve the milk supply of his community through legislation and other ordinary means, devised the plan for a commission consisting of medical men, which, by voluntary supervision and control of methods, by paid expert inspection of dairy work, and by their certification of the product, should undertake, in cooperation with dairymen possessing the requisite intelligence and capital, to make available a supply of milk produced under regulations imposed by themselves, which should fulfil the most exacting requirements of the physician.

[4] Dr. Coit's writings are freely quoted without definite reference.

Under the leadership of Dr. Coit, the first medical milk commission was organized in 1893, in Essex County, New Jersey. The term "certified milk" was coined to designate the milk produced under the control of this commission, and was protected by United States copyright. In addition to this, many states have since passed statutes prohibiting the use of the term except on the authority of a properly constituted commission. The movement, originally designed by its author to meet the dire necessities of his own neighborhood, was so successful that similar commissions were organized elsewhere—in New York in 1896, in Philadelphia in 1897, and since then throughout the country—until there is now a total of not less than sixty commissions in twenty-three states, and two in Canada. New York leads with ten, Ohio has six, while California in the extreme West and Massachusetts in the East each have five. The American Association of Milk Commissions was organized in 1906, to institute better methods of propaganda and to unify the work of its component commissions. In California there is also a state association which aims to keep the work within its jurisdiction on the same high plane.

The influence of these commissions has been so profound, not only within the limits of their own immediate activities, but in relation to the improvement of the general milk-supply and all other food products, that they may be classed as one of our most important agencies in public health work; and Dr. Coit, through whose continued ardent advocacy of the cause of pure milk thousands of babies have been saved from needless sickness and death, may properly be named among our great medical philanthropists.

The first step in the acquisition of a supply of certified milk in any community is the organization of a milk commission. This should consist of about five physicians, selected by the county medical society solely because of their known interest in all that the pure milk movement stands for, and perhaps a public-spirited attorney or one or two other lay members should be added to it. Their term of office should be five years, for experience in the work is essential for useful service on a commission, and the personnel should be changed as little as possible. The members receive no pay, and the expense of the work, the fees of the experts, printing, etc., are provided for by a system of assessments on the dairies certified.

An approved and trustworthy dairyman, with financial ability and adequate dairy facilities must then be found, who will agree, in consideration of medical support and an increased recompense in the price of his product, to conduct his dairy, collect and handle the milk in conformity with the requirements of the commission.

Formerly, each commission fixed its own requirements and naturally there resulted a great variety of standards. The code of the American Association was adopted last year only after the most painstaking consideration of its provisions by a committee of able and experienced members, and it may be held to represent the most authoritative conception of the conditions under which milk should be produced for certification. Membership in the association will hereafter depend on acceptance of and compliance with this code, and it is hoped that the heretofore heterogeneous standards of the various commissions will soon be obsolete.

The duties of the members of the commission shall be to enforce the regulations, which, in the code referred to, cover in minute detail every phase in the production of certified milk; to be responsible for personal inspection of the dairy and distributing stations at such intervals as will serve to keep them thoroughly in touch with the management; to provide for competent expert examination of the herd by approved veterinarians, and bacteriologic and chemical analyses of the milk at proper intervals; to maintain such supervision over all matters pertaining to the health of employees as will protect the milk against contamination by pathogenic organisms from those engaged in handling it; and to advance the doctrine of pure milk by private precept, by public lectures, exhibits, literature and all other available means.

The control of the commission over the dairy and the entire process of production and distribution of the milk must be absolute. The hygiene of the dairy is the first consideration. The terrain of the farm must be such that it is well drained and the paddocks and yards shall be kept clean and dry. Rubbish and stable dirt shall not be allowed to accumulate nor shall any insanitary condition be permitted. The water-supply must be pure and ample.

The dairy buildings must be located at a sufficient distance from other buildings, toilets or latrines. dusty roads, cultivated and dusty fields, or other possible sources of contamination. If unavoidably exposed to dust the buildings must be screened with cheese cloth.

The stables must be so constructed as to facilitate the prompt and easy removal of waste products. The floors must be made of non-absorbent material, must be properly graded and drained and have cement gutters at least six inches deep to catch and carry off all manure and drainage. The walls and ceilings should be planned to avoid lodgment of dust and dirt. At least six hundred cubic feet of airspace should be allowed for each cow, with not less than four square feet of window area. The buildings must be screened to prevent the entrance of flies, rats, and other vermin. The greatest cleanliness must be maintained about the premises at all times, the stables are to be washed out twice daily, and all feed and water-troughs kept clean and sanitary.

The proper selection of cows for a certified herd is a matter of importance, a proper admixture of animals of different breeds being frequently necessary to maintain the requisite fat standard. The productivity of each cow in a herd should be recorded and the unprofitable ones weeded out, as a few such in a herd lower its average output very appreciably and entail financial loss to the owner. No cow should be admitted to a certified herd until its freedom from tuberculosis or other disease has been determined by the veterinary expert of the commission, and the entire herd must be subjected semi-annually to a rigid tuberculin test, which shall conform to the rules and regulations of the United States government with respect to tuberculin testing.[5] Veterinary supervision must be maintained at all times and sick cows at once removed from the herd and quarantined or destroyed as the nature of the illness may require. In California there is what should be regarded as a valuable rule in relation to the exclusion of tuberculosis from the herds, namely, when a group of animals from one source is examined for admission to the herd, if more than 10 per cent. react to tuberculin, the entire group is rejected. We do not believe it safe to admit to a certified dairy even non-reactors from herds known to be extensively infected, as this will almost surely permit animals in the incipient stage of the disease to gain entrance. Each animal is identified by a numbered ear-tag or other mark, and a descriptive record is kept of distinctive markings, dates, results of tuberculin tests, etc.

---

[5] Circular of instructions for making tuberculin tests, U. S. Bureau of Animal Industry.

Cows should be kept clipped and before each milking must be thoroughly cleansed by brushing and washing, the udders especially being washed clean and dried. All utensils used in handling the milk must be sterilized, and the milkers must wear clean washable suits and carefully cleanse their hands before milking. One of our Western dairies under probationary certification during the past year, has been using milking-machines with which great difficulty was at first encountered in keeping down the bacterial counts, but this is apparently being obviated by experience and minute attention to detail.[6]

The milk must be strained, cooled and bottled immediately after being drawn and the bottles sealed with a cap bearing the name of the dairy and of the certifying commission, together with the date of production or of permissible delivery. The bottles must then be packed in ice in suitable containers for shipment and must reach the consumer within thirty hours, the temperature at the time of delivery not to exceed 50 F.

Chemical and bacteriologic examinations of the milk are to be made at least weekly, and in the event of any deviation from normal standards, tests shall be made daily until the discrepancy has been corrected. If this cannot be accomplished within ten days, certification shall be withdrawn. So delicately balanced may be the organization of a certified dairy and its success so dependent on perfection of technic, that I have known the sudden loss of a cleaner to be at once discovered by the bacteriologist, the added work thrown on the remaining hands and the slight relaxation in methods having resulted in an immediate rise in bacterial content.

The methods that must be followed in carrying out the chemical investigations essential to the protection of certified milk are so complicated that, in order to keep the fees of the chemist within moderate limits, those procedures must be eliminated which are not strictly necessary to demonstrate the quality of the milk. For this reason the determination of the water, the total solids and the milk-sugar is not required as a part of the routine examination by the code of the American Association.

The fat standard is fixed at 4 per cent., with a permissible range of variation of from 3.5 to 4.5 per cent., while the standard for certified cream is 18 per cent., with an allowed variation of 2 per cent. in either direction. The tests recommended are the Babcock, the Leffmann-Beam, and the Gerber.

The protein standard is fixed at 3.5 per cent., with a permissible range of from 3 to 4 per cent., to be determined by the Kjeldahl method, the Gunning or other reliable modification being used, and the factor 6.25 being employed in reckoning the protein from the nitrogen. The protein determination may be omitted except when some special condition renders it desirable.

The chemical examination also includes tests for adding coloring matter and preservatives, among the latter being formaldehyd, borax, boric, salicylic and benzoic acids, and salts of the latter; and tests to determine if the milk has been heated. The specific gravity should be between 1.029 and 1.034.

The bacteriologic standard of the American Association is not to exceed 10,000 bacteria per cubic centimeter of milk, and the presence of pathogenic bacteria excludes the milk from certification. The samples to be examined must be collected by a representative of the commission, in original packages as offered for sale and they must be kept iced until plated, which shall be not later than forty hours from time of milking. Because of the great variation in methods for the bacteriologic examination of milk and the divergent results thereof, the methods to be followed in the examination of certified milk, the composition of the culture mediums, the technic of plating and the period of incubation are all carefully specified, thus affording a proper basis of comparison between milks from different sources. The experts of the commission are required to render written reports of each examination made by them, these to be kept on file in the office of the secretary.

The milk laboratory is a development of the pure milk industry which now, in a number of our cities and in connection with certified dairies, affords the physician an opportunity to order for his little patients milk formulas much more accurately compounded than is possible by home modification, which is a very great advantage in infant-feeding.

The conditions under which certified milk is produced make it impossible that it shall ever constitute a large part of the total milk-supply. As long as we continue to use milk in its natural state, however, we may feel sure that no higher grade of milk can be obtained and that certification will continue to exert an ever-increasing good influence. The one disadvantage urged against it is that of its higher cost in comparison with ordinary milk. This is apparently a valid objection, but it may be stated that in no other combination of foods obtainable in the markets can the same food value be obtained for the price which certified milk commands. The objection, therefore, is more apparent than real.

Chief among its advantages are its known and constant chemical composition and nutritive value; its relative freedom from bacteria of any sort and its practically absolute freedom from pathogenic organisms; its early delivery to the consumer in sealed and iced containers; its purity and freedom from adulteration; and its consequent adaptability to the dietetic requirements of children and invalids.

That these qualities are assured by the guarantee of physicians actuated solely by philanthropic motives in their milk commission activities, merits for certified milk the confidence of the profession and the public. We feel, therefore, that we may expect the unqualified support, especially of pediatrists, and of all those who are interested in the public health.

## ABSTRACT OF DISCUSSION

**Dr. J. W. Van Derslice**, Chicago: I am not a Holstein man, I am a Brown-Swiss man. In the pure-bred Holstein it is practically impossible to run a uniform fat percentage. There is no animal in which atmospheric changes, fright, etc., affect the contents of the milk so much as in the Holstein. Last fall we had a severe thunder-storm; the following day the fat of the Holstein farms dropped to 2.6 per cent. The thunder-storm did not last over fifteen minutes.

Another thing to be considered is the milk-machines. We had one farm with milk-machines and we did not have any trouble with the bacteria count. After we had educated the milkmen to the certified-milk plan they turned out milk of very low bacterial count. We did find that veterinary examination of that herd was important. It was necessary to examine the herd weekly, and practically every time it was necessary to throw out one or more animals on account of mastitis. So the milk-machine was discredited. I hope that next year I can tell you that the milk-machine is the only thing to use. One of the other farms is putting in milk-machines, and we hope that improvements have been made in this machine so that it will not develop mastitis. If we could get machines that would not cause disorder of the udders, the question of the production of sanitary milk would be answered.

---

[6] Since writing this paper, certification of this dairy has been canceled.

Dr. Henry L. Coit, Newark, N. J.: In connection with the initial steps made to secure certified milk, I wish to say that unaided I could never have accomplished it. Without the cooperation of the producer my work in the beginning would have been negatived. Had it not been for the loyal cooperation of physicians my plans would have failed. The name of the dairyman who produced the first quart of certified milk should be recorded in history. It is Stephen Francisco. Without the practical dairyman, the medical milk commission could accomplish little.

Had it not been for the loyal support of the representative medical milk commissions this association would not have been founded. Geier, Freeman, Hamill, Tuley and Myers gave the impetus in founding this movement. I wish simply to supplement the kindly reference to me by mentioning the names of others who did constructive work.

Dr. John Zahorsky, St. Louis: In St. Louis we have met great difficulty in keeping the bacteria count down to 10,000 because of the hot weather. Generally we have it down even below this, but in spite of the same care it will run up. The commission has insisted on uniform standards. I still think that there will have to be some variation in standard in order to meet climatic conditions. So far as the effect on the infant is concerned, it does not matter whether the bacteria count is 10,000 or 30,000. There will have to be a minimum and a maximum count, and not a definite fixed line.

Dr. Thomas C. McCleave, Berkeley, Cal.: I do not believe that a dairy which produces milk only under 30,000 has any right to ask for certification by milk commission in any part of this country. The work of North in New York state is probably familiar to you all. We know that he teaches that, under almost any conditions of environment, almost any intelligent dairyman can produce milk of a lower bacterial count than 10,000. In my cities the ordinary market milk is crowding certified milk very closely in the matter of bacteria count, and for us to have on the market in any city a certified milk in which we insist that this count come down to only 30,000 would be most mortifying, when you consider that in that city ordinary market grades of milk may be found to have lower bacterial counts than certified milk. Any dairyman who is not willing to produce his milk under conditions which will guarantee an average of 10,000 or less should not produce certified milk. We have no difficulty in keeping the count below 10,000. Our dairymen themselves would be mortified if we suggested that they come down only to 30,000. The matter of uniformity of standards is, of course, a debatable question. The object of the American Association of Milk Commissions, as I understand it, is to assure to physicians who are not members of the association of milk commissions and the public that when they ask for certified milk in New York or Brooklyn, or Chicago, or San Francisco, or anywhere they know what they are getting. The bacterial count, the care of cows for protection against tuberculosis and all the requirements should be the same. It is even true in this country that there are commissions putting the stamp of guarantee on milk from cows which have not been tested for tuberculosis. The whole propaganda of the milk commissions is discredited by one commission of this kind. We do not expect that every commission will be able to come up to our standards absolutely. In various parts of the country climatic or other conditions may make it impossible to do this; but all we ask is that the commission come up to the standard to the best of its ability. If we have an honest commission the result will be fairly good. When commissions are willing to give their names to something concerning which they know nothing, then we have a product which is misbranded and should come under the ban of the pure food laws. Some members of commissions do not know what certified milk is. That is the reason I wrote this paper—there is so much ignorance as to what certified milk is. In some parts of the country the laity are much better informed along this line than the physicians.

Mr. Stephen Francisco, Fairfield, N. J.: Our plant does not produce certified milk only. The idea is to make certified milk safe for infant feeding, and I pity the producer who does not consider infant feeding above everything else. It takes more than the cattle there to produce the milk desired. The herd has to be examined every day. There is hardly a day that some cow is not taken from our herd for one reason or another, generally not to return. We are learning something every day, through the suggestions of our physicians, bacteriologists, chemists and veterinarians—every one of whom is giving thought to this matter. Certified milk costs between 12 and 13 cents a quart.

Mr. W. E. Miller, Lebanon, Ohio: The cost of certified milk may be estimated in percentages as follows: Wages, 28.26; supplies, 2.40; stable hauling, .31; power and refrigerations, .58; repairs, 1.31; freight, 5.46; feed, 47.23; cost of certification, 8.42; miscellaneous, 4.79; bedding, 1.24.

I have taken the cost of milk from our books for 1912. This covers one year, and I have taken the total cost of all the items that should enter into the problem and have reduced them to percentages.

There is no uniform system of accounting among the producers of certified milk. Each man must take into account local conditions. It is rather hard to compare the results of two men. Perhaps this can be worked out in the near future. If we can arrive at a uniform way of accounting it will help to clear up the cost of production. We know that in some places the production of certified milk is a fad. Men with more money than they need select this method to get rid of it. It seems to me that philanthropy and business do not mix well. If this movement for the production of certified milk is to succeed, it must be put on a sound economic basis. We do not advance far in any business unless the firm profits, and these profits should include a proper compensation for everyone concerned. I have heard of certified milk selling for from 12 to 20 cents a quart. If the milk is the same all over the United States as it should be, then why this difference in price? Some men say that they cannot afford to sell certified milk for 12 or 16 cents. Perhaps there is something in their organization that needs improvement. We should first be sure that we have approximated 100 per cent. efficiency and then, if the price of certified milk is not sufficient to give a fair compensation, it is time to ask for an increase in price. All fair-minded producers are trying to reduce the cost as much as possible. We have organized our force into three divisions —a cleaning division, a feeding division and a milking division, in order to get 100 per cent. efficiency.

The cost of certification, including the cap as well as the inspection, is 8.42 per cent. I think that the consumer should not be burdened with the unnecessary cost of supervision and capping. We should try to secure trustworthy men, so that the milk need not be kept under lock and key. We must, of course, protect the public as much as possible. After the public is protected our supervision should stop.

Another thing that increases the cost of certified milk is the appearance. We have to take into account the psychology of the situation. Things have to look clean as well as be clean. Can anybody tell me in what respect a white suit is any cleaner than a blue suit or a black suit? It simply looks cleaner. If we are to spread this gospel of certified milk among the consumers, among physicians, we must appeal to the eye. The bacteria count may be good, but the people cannot see the germs; they can see the color of the suit, which may have nothing whatever to do with the bacteria count. That is one thing that keeps up the cost of production. The thing that appeals to me is the advantage of bringing certified milk within the reach of the greatest possible number.

These cost items do not include distribution. The milk is in Cincinnati, the freight is paid, but the milk has not yet been distributed to the consumer. This certified milk is distributed with the other milk. It is, therefore, impossible for us to distinguish the cost of distributing certified from other products. If we had nothing but certified milk it would be easier.

**Dr. Otto Geier**, Cincinnati: Will you analyze the cost of certification?

**Mr. Miller**: It includes cap and inspection by the veterinarian, inspection by the bacteriologist and chemist and all charges of that nature.

**Dr. J. W. Van Derslice**, Chicago: What is the price per pint?

**Mr. Miller**: Four and three-quarters cents. Wages and repairs and freight are all higher on certified milk than they are on common milk, and feed also is higher.

**Dr. T. C. McCleave**, Berkeley, Cal.: Mr. Miller has not answered the question adequately. A large part of the cost of certified milk, as compared with ordinary milk, is dependent on the addition of the actual expense of certification. It depends also on the greatly increased running expenses of the dairy. For instance, the matter of putting in steam sterilizing plants and sterilizing every utensil that is used, requiring men to wear clean suits, which have to be provided and laundered. The cost of tuberculin testing and the cost of the animals destroyed when found to be tuberculous are large items. All those items enter into the question over and above what Mr. Miller specified. If a dairyman started to produce an equal grade with certified milk, irrespective of any relation to the commission, his expenses leaving out fees, would be higher than those of the man who produces in the ordinary way.

**Dr. J. W. Van Derslice**, Chicago: In Chicago the milk is produced practically under two contracts. Under one the man furnishes the bottle, label and certification and sends the milk f. o. b. to Chicago for 12 cents. The distributor orders a certain number of bottles each day. The other contract, which brings the cost of certification and the cost of distribution more clearly before you, is, I believe, the best one. There are four or five firms under contract to distributors, who agree to take the entire output of the firm at 8 cents a quart net, the distributor furnishing the labels, paying the cost of certification and buying the bottles. On that 8-cent basis, the farmer—and the farmer I am speaking of knows how to figure costs—says he is getting $2 a hundred for common milk. In other words, he says the difference between the production of certified milk and the production of commercial milk is that, if he sells his milk as a commercial milk, with the lessened cost which that entails, he would sell it on a graduated scale running from $1 to $1.70 per hundred. For the year 1911 the average was $1.67. For the year 1912 it was a little higher. This man says that he is selling his commercial milk for $2 a hundred. In other words, the men who figure the cost for us most closely tell us that there is a leeway of 40 cents per hundred pounds, or 40 cents per 46 quarts, between the production of certified and commercial milk. This philanthropy then is a fine text for a sermon. They do not talk that to me any more. The men who went into this business first have their money tied up in a big plant. They knew nothing about what the possibilities were for them, but the man who goes into the business to-day does so as a money-making proposition, because there is a market for the product. The rich man wants some place to take his fine friends, and the only possible way to make the farm pay is by the sale of certified milk. There is absolutely no question about it. The big farm to-day that is not selling its entire output is losing money. According to the government reports, over 50 per cent. of the farms are losing money to the owner every day.

Another point I wish to bring out is the value of the superintendent. We can show you superintendents who have changed from one farm to another, and the bacteria count follows the superintendent. You must have a man who knows, feels and breathes certified milk. Another point Mr. Francisco spoke of—in one-half or two-thirds of our farms a prize is held up to the employees on the farm—a bonus of $5 a month if the bacteria count during the month is under 5,000. In that way you have every worker on the farm watching his coworker to see that there is no carelessness. Every man wants that $5.

**Dr. Otto P. Geier**, Cincinnati: There is nothing about which there is so much confusion as the cost of certification. I attempted several years ago to make a survey of the methods used by the different commissions of the country and to define in my own mind, at least, the broad problem of the cost of certification. There are just as many methods of arriving at the cost of certification as there are milk commissions in the country. One commission charges a per bottle tax and supplies nothing but the chemical and bacterial work and veterinary inspections. The next one charges a flat rate for each bacteriologic chemical and veterinary examination, and the producer buys his caps. In still another instance the producer pays a per bottle tax and the chemical, bacteriologic and veterinary inspections are made by the commission. The commission also buys the caps and seals out of the per bottle tax income. So you have just as many variations in the matter of arriving at the cost of certification as you have commissions. I have not seen the figures shown here before. At first sight they seem unreasonably high. I should remark, however, in the interest of Cincinnati that the commission does many things for the producer. It supplies the caps and seals, medical inspections, veterinary inspections and chemical and bacteriologic examination, which are done biweekly, and more frequently if there is any trouble at the dairy. The commission is able to maintain a laboratory for this work in connection with the office of the commission. The bacteriologist and chemist and his assistant, as well as the medical profession of the community, are at the call of the dairymen. The commission also does propaganda work, thus advertising the product of the dairymen and in a general way serving the community from a broader point of view. Everything else being equal, it is fairer to use a per bottle tax than a tax which applies only to the various examinations. In a per bottle tax the large producer helps pay the load of the smaller producer.

**Mr. W. E. Miller**, Lebanon, Ohio: The cost of keeping up the herd is based on the assumption that the herd is practically stationary. Individuals go out, but others come in. We have practically no loss from the tuberculin test. As a matter of fact, the herd increased in value during the time under discussion. As to repairs, our aim is to keep the equipment in the original condition. It is practically as valuable now, because of improvements made from time to time, as it was in the beginning.

# PATHOLOGY OF THE PROSTATE *

E. O. SMITH, M.D.
Professor of Genito-Urinary Surgery, Medical Department of the University of Cincinnati
CINCINNATI

Sixty-eight years ago Samuel D. Gross[1] stated that the prostate gland consists of "two lateral lobes and a small pyramidal tubercle, which is a small portion of the gland in a state of hypertrophy, described as a third lobe by Sir Edward Home."

In Keen's edition of "Gray's Anatomy" published in 1887 I find that the prostate has "two lateral lobes of equal size separated by a notch. A third or middle lobe is a small transverse band, occasionally a rounded or triangular prominence placed between the two lateral lobes.

---

* Read in the Section on Genito-Urinary Diseases of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

[1] Gross, Samuel D.: Elements of Pathologic Anatomy, Boston, 1845.

According to Gerrish[2] the prostate consists of two lateral lobes.

In Cunningham's "Anatomy," 1903, we find the following statement:

> The somewhat wedge-shaped portion of the prostate, which lies between the ejaculatory ducts and the posterior aspect of the urethra receives the name of the *middle lobe*. . . . The rest of the prostate is described as being composed of two large lateral portions or *lateral lobes*."

White and Morton, 1907, say that "the prostate is made up of two lateral lobes connected by an isthmus."

Many more authors of comparatively recent date could be quoted, using about the same language in each case, namely, that the prostate is made up of two, or at most three, lobes, with no definite or comprehensive description of their relations. Nothwithstanding the fact that much good research work has been done on this subject by several investigators, it seems to have encountered the same difficulty of most new subject-matter in penetrating the covers of the average text-book. It is kept from their pages because there is no room remaining after the stereotyped matter that has been handed from generation to generation is given its accustomed place of prominence.

Among those who have developed the embryology, histology, anatomy and pathology of the prostate so that now we have a definite knowledge of this subject that can be accepted are Young, Geraghty and Stevens, 1906, von Frisch, 1910, Tandler and Zuckerkandl, 1911, and Lowsley, 1912.

While many others have studied this subject in detail and have published excellent monographs, it seems to me that these four reports which have appeared in the last seven years cover about all that is of value pertaining to these phases of the prostate gland. When some one works out a definite etiology of prostatic hypertrophy the last chapter on the prostate gland will have been written.

In view of the fact that most of the data on this subject are of recent date it seemed advisable to present at this time a summing up in concise form a sort of working knowledge and to further stimulate a more general interest in this important region of the body.

That there may be no confusion as to terminology it seems advisable that a definite understanding be had regarding the various portions of the gland. According to Lowsley these are as follows:

> The middle lobe, or that part of the gland which is situated between the bladder and the ejaculatory ducts under the floor of the urethra (prespermatic and posturethral). Lateral lobes or those parts of the gland which arise from the prostate furrows and the lateral walls of the urethra and extend laterally and posteriorly from that structure. Posterior lobe, or that part of the prostate which lies dorsal to the ejaculatory ducts above their entrance into the urethra and dorsal to the urethra below this point (postspermatic and posturethral). This is the part of the prostate which is felt per rectum. Ventral lobe, or that part of the organ formed by glands arising from the anterior or ventral wall of the prostatic urethra.

## EMBRYOLOGY

Lowsley's investigations of the development of the prostate gland consisted in serial sections of prostates and surrounding tissues obtained from human fetuses varying in age from 10 weeks to full term. He found that the prostate gland begins to develop during the third month of fetal life.

> The tubules which compose it make their appearance as solid epithelial outgrowths from five distinct parts of the prostatic urethra. These solid masses of deeply staining cells very soon become circularly arranged around the lumen, and branches are found very early. The five foci from which groups of prostatic tubules take their origin are located as follows: on the floor of the urethra between the neck of the bladder and the openings of the ejaculatory ducts and utriculus prostaticus, one in each prostatic furrow and on the sides of the urethra, on the floor of the urethra below the openings of the ejaculatory ducts and the utricle, and on the ventral or anterior wall of the prostatic urethra. The tubules originating from these five foci by their further growth and the development of the stroma around them become the middle, right and left lateral, posterior and anterior lobes, respectively. In early fetal life they are widely separated from one another, but in later stages the separation between the middle and two lateral lobes is not very great. There is not an intermingling of tubules in any of the specimens studied, but in many places in the new-born the tubules of the middle lobe are observed side by side with those of the lateral lobes, there being no definite capsule separating them. The separation of the posterior lobe from the others is complete, as there is a rather dense layer of fibrous tissue between it and the lateral lobes. The anterior lobe is widely separated from the two lateral lobes.

There is but little difficulty in demonstrating these five lobes in post-mortem specimens, or in the prostates removed entire, during life.

## HISTOLOGIC ANATOMY

The prostate reaches its full normal development about the twentieth year. The capsule or external portion is not a true capsule in the sense that it can be easily separated from the gland, but it is made up of musculoconnective tissue from which bands extend into the body of the gland surrounding the alveoli of the glandular structure. The various lobes normally have no distinct capsular separation from each other. The gland tissue communicates through numerous duct openings with the posterior urethra. It is through these openings and along the tubules that infection easily finds its way into the prostate gland from the urethra.

The prostate is in close relation with the bladder, it surrounds the urethra, is attached to the pubic arch and is very narrowly separated from the rectum. A dense plexus of veins partially envelops it.

## PATHOLOGY

The most frequent cause of prostatic disturbances is the gonococcus which invades the glandular structure from a posterior urethritis. The prostatitis thus produced may be simple and confined to small areas or it may be quite general involving a large portion of the gland. There may be only an acute inflammatory condition produced or there may be abscess formation. In the latter the abscess or abscesses at times develop very early, as soon as three weeks, following the infection of the posterior urethra. It occasionally happens that about the time the abscess on one side of the prostate has been cared for there develops another on the other side.

Many cases of gonococcic infection of the prostate cause but few symptoms, yet the gonococci are resting quietly to be aroused from their lethargy following a period of dissipation and excesses by the one harboring them. Or possibly he has been contemplating matri-

---

2. Gerrish, Frederic H.: In Text-Book of Anatomy, Philadelphia, 1899.

mony and has been on his good behavior, indulging in neither alcohol nor sexual gratification for months; yet shortly after marriage a urethral discharge develops, and too often an innocent wife becomes infected from a well-meaning but still infectious husband.

The prostate must not be held responsible for all such late infections, however, for the seminal vesicles are more frequently infected than was formerly supposed. Owing to the close relation between the prostate and seminal vesicles it is very difficult to state when one is involved and not the other. In many post-mortem specimens examined I have found a perivesiculitis so pronounced that it was no easy matter to determine by touch where the prostate ended and the vesicles began. I am convinced that we have often made the mistake of diagnosing prostatitis when in fact it was seminal vesiculitis. That it is possible for the vesicles to be pathologic with a normal prostate has been proved several times in the post-mortem specimens examined. Most of my material was gathered from the Cincinnati City Hospital, and normal seminal vesicles were rare.

Tuberculosis of the prostate may be primary, but is in most cases secondary to tuberculosis elsewhere in the body, and is usually secondary to tuberculosis elsewhere in the genito-urinary tract. Most frequently tuberculosis of the kidneys or epididymes precede invasion of the prostate. Among the cases that I have been able to examine post mortem there has been found only one of tuberculosis involvement of the prostate in which the seminal vesicles have escaped the same infection. Often it is the seminal vesicle and that side of the prostate corresponding to the epididymis, right or left, that is involved. Since tuberculosis of the prostate is seldom if ever the primary focus of urogenital tuberculosis and is almost always associated with tuberculosis of the seminal vesicle, the futility of surgical treatment can readily be understood. In these cases it is also frequently difficult to locate on rectal examination the upper border of the side of the prostate involved, as it is coalesced with the seminal vesicle by new inflammatory tissue.

Calcareous deposits are not infrequently found in the prostate in late adult life. This may be in the form of small accumulations of calcareous material disseminated through the gland, or a single large calculus, or a pocket containing many hundred small calculi.

## SENILE CHANGES

Many men past 50 years of age have urinary disturbances. The large majority of these are due to pathologic changes in the prostate gland. Nevertheless it must not be taken for granted that because a man is more than 50 and has urinary trouble, that it is necessarily due to the prostate. Recently a man aged 62, who had been treated for hypertrophy of the prostate for some time, was referred to me for operation. His troubles were all due to a very tight stricture in the bulbous portion of the urethra which had developed subsequent to a gonorrheal urethritis contracted more than twenty years previously.

Senile changes from the normal morphology of the prostate are three: (1) adenoma, new growths in the glandular stricture; (2) increase in the relative amount of stroma, fibrosis, and (3) malignancy.

Any one or all three may be present in a single case. In the very large prostates there is an enormous development of adenomatous tissue with practically no increase in amount of the stroma or musculoconnective tissue. This variety can easily be felt per rectum and is not hard.

When the interglandular tissue, the stroma, is unduly increased in amount the obstruction is not so large and feels hard.

Of the five lobes all may undergo these morphologic changes classified as hypertrophy, except that portion below the ejaculatory ducts, the posterior lobe. The most frequent origin of adenomatous growth is in the middle lobe, just beneath and behind the internal urethral opening. The anterior group of glands or lobe is seldom involved in this process, the lateral lobes rather frequently. Tandler and Zuckerkandl in their study of many post-mortem specimens of prostatic hypertrophy always found the middle lobe involved. While I am not in a position to say that enlargement of the lateral lobes are not always attended by morphologic changes of the middle lobe, I do know that many patients have been clinically cured on removal of later enlargements when no middle lobe could be felt. There is an endless variety of shapes and contours of these new growths, and their effect on the posterior urethra and the internal urethral orifice is varied. That portion of the urethra between the collicle (verumontanum) and the bladder is elongated and distorted in many ways, being flattened, twisted and pushed to one side or the other of the middle lobe.

The gland, which normally is entirely extravesicular, becomes both extravesicular and intravesicular, the enlargement pushing up into the bladder around the vesicle orifice. The sphincter vesicae is crowded from its normal position about the internal meatus and is found surrounding the intravesical portion of the new growth. In its normal state this gland can be felt per rectum, but in no way intrudes on the rectal lumen. Many hypertrophies become so large that they act as a decided rectal obstruction.

A few of our specimens show a distribution of adenomatous growths entirely around the urethra, involving the anterior, two lateral and middle lobes. These are the rings or urethral collars that are very troublesome to the patient and are difficult of removal.

The so-called "prostatic bar" is either not prostatic or not a bar. In the first instance it is a fibrous bar which has developed about the internal sphincter as a result of chronic inflammation in the posterior urethra and occurs earlier in life than true prostatic changes. In the second instance if the obstruction is of prostatic origin it is not in the form of a bar, but is an enlargement of the middle lobe, and changes the shape of the internal meatus from a normal funnel appearance to that of an inverted crescent.

As was mentioned earlier in this paper there is no true normal prostatic capsule from which the prostate can be removed. The surgical capsule which surrounds the adenomatous growths is the prostate crowded to the side during the development of the adenomata. This when examined microscopically shows both stroma and gland tissue closely compressed. Squiers has called our attention to the ease with which the line of cleavage or separation between the surgical capsule and the new growth can be found, when we seek for it in the roof or anterior portion of the prostatic urethra. In the large majority of cases there is nothing but mucous membrane covering the new growth at this place. There are some cases in which this is not true, and these are difficult of removal.

Not infrequently a patient with marked prostatic symptoms, whose prostate feels very large, is relieved of his trouble and the gland noticeably reduced in size after a few days' rest in bed, free catharsis and continuous bladder drainage. The symptoms were due to an acute engorgement or stasis in the prostatic venous plexuses, and when the predisposing causes of this were removed the symptoms disappeared. If allowed to go without surgical interference, as he should be, the patient may live comfortably for a long time without further trouble.

I am not yet convinced that a simple prostatic hypertrophy has any tendency to undergo a malignant degeneration; hence cancer is not to be feared as a later development of hypertrophy. If the patient has cancer of the prostate his trouble began as a malignancy and did not become such after he had suffered many years from an adenomatous overgrowth.

The posterior lobe is the locus of origin of practically all of the malignancies of the prostate, which are simple carcinoma, adenocarcinoma or sarcoma, the latter exceedingly rare. It is possible for the same patient to harbor both hypertrophy and cancer, since these two pathologic processes attack different parts of the gland.

Cancer originating in the posterior lobe soon obliterates the natural groove or furrow felt in the prostate per rectum. The disease may be confined to the gland or invade the surrounding structures. In one case of far-advanced carcinoma of the prostate I found, when doing a palliative operation, a degeneration or breaking down of the periphery of the cancer, and a solid mass of cancerous tissue was removed without dissection, decapsulation or cutting, as it was retained in this space much as a foreign body.

## CONCLUSIONS

1. The prostate gland has five distinct glandular areas, which may be termed lobes.

2. Pathologic changes in the seminal vesicles are often overlooked and the prostate alone considered, when in fact both are involved.

3. Tuberculosis of the prostate is seldom found without the same infection of seminal vesicles.

4. Prostatic hypertrophy is usually a simple adenomatous growth which crowds the normal prostate, so as to form a surgical capsule. In the roof or anterior portion of the prostatic urethra these new growths are covered with but little more than mucous membrane.

5. Malignancy of prostate is confined to the posterior lobe.

19 West Seventh Street.

## ABSTRACT OF DISCUSSION

Dr. John T. Geraghty, Baltimore: Our ideas regarding the pathology of hypertrophy of the prostate have changed considerably in recent years. At first, it was considered that the adenomatous process involved the whole prostate, but now it is quite generally conceded that the entire gland is not involved in the pathologic process. Albarran and Motz some years ago concluded from their studies that only the central portion or the central group of glands was the seat of hypertrophy. More recently, Tandler and Zuckerkandl brought forward the view that hypertrophy involved only the middle lobe, and this view seems to be accepted almost universally. At present the prostate at birth and in the adult is composed of (1) a posterior lobe which forms the largest part of the prostate, as felt by rectum; (2) the two lateral lobes which are fused beneath the urethra with the embryologic middle-lobe tubules; (3) the anterior lobe which in the adult prostate is usually insignificant and contains only a few scattered glands, and (4) groups of accessory glands, one group lying beneath the mucous membrane at the vesicle orifice inside the sphincter and usually referred to as Albarran's glands. Another group of glands described by Home is occasionally found beneath the mucous membrane of the trigon. This latter group is much more inconstant than the Albarran group. From my studies of prostatic hypertrophy, I am forced to disagree with Tandler and Zuckerkandl that hypertrophy originates only in the middle lobe and that the lateral masses take no part in the process. In an examination of cases of very early hypertrophy, it is possible to demonstrate the presence of the adenomatous nodules in the lateral lobes, when none are present in the portion corresponding to the median lobe. The median and lateral lobes are, as a rule, equally involved in the pathologic process, while the posterior lobe is the only part of the prostate which does not take part in the hypertrophy. As I have previously pointed out, this posterior lobe plays an important rôle in cancer of the prostate. When carcinoma arises in a prostate previously the seat of a benign hypertrophy, it does not result from the degeneration of the benign adenomatous tissue, but begins in the posterior lobe, which is the non-hypertrophied portion. The recognition of this fact is important in both the diagnosis and radical treatment of cancer of the prostate.

Dr. Bransford Lewis, St. Louis: Ten years ago I called attention to the wide variations that occur in these obstructions in connection with hypertrophied prostates and their bearing on the choice between suprapubic and perineal prostatectomy. At that time I argued that there were some cases that demanded suprapubic prostatectomy, others that demanded a perineal operation and others that demanded no operation. It depended on the types that Dr. Smith has so graphically described. Later studies have, I think, confirmed that position, and I still believe that it is the proper one to take in relation to the choice of operation.

# CHRONIC CYSTITIS IN WOMEN NOT A DISEASE *

### GEORGE GILBERT SMITH, M.D.

BOSTON

The demonstration to this section of the thesis that persistent cystitis in women is in itself not a disease, but is the result of pathologic conditions outside the bladder, strongly resembles the importation of coal into Newcastle. That this conception of cystitis is not generally held by medical men, however, has been illustrated many times in the women's room in the genito-urinary outpatient department of the Massachusetts General Hospital. A number of cases diagnosed as "cystitis" and accompanied by a too long-deferred request that they be studied have been sent there, not only by outside practitioners, but in some instances by other departments. With practically every one of these patients, the time spent in useless bladder lavage had been wasted, and in some the delay had been even more injurious because of the headway which it had afforded the disease.

Every urologist knows that the normal bladder is extremely resistant to infection. Only when its mechanics or its circulation are disturbed, or when it is continuously flooded by infected urine from the kidneys, does it succumb to bacterial invasion.

Proof of the resistance of the bladder to infection may be found in the rarity with which cystitis follows catheterization or even cystoscopy of the normal bladder. Williams, Murray and Wallace[1] found colon bacilli in the urine of twenty-four women in twenty-six, after

[1] Williams, Murray and Wallace, Liverpool Med.-Chir. Jour., 1912. No. 62, p. 425.

operation, yet none of them had cystitis. Not only is the bladder resistant to new infection, but inflammation of long duration will frequently clear up with surprising rapidity, once the cause of it is removed.

It is not my contention that simple cystitis never occurs. In my series, there is one case of syphilitic cystitis. Acute trigonitis, frequently mistaken for cystitis, may follow infection by the gonococcus. Inflammation may, and usually will, result from the intense congestion caused by the too sudden emptying of an overdistended bladder. The trauma of childbirth reduces the resistance of the bladder to those bacteria which ordinarily would pass through it without effect.

It is my belief that these cases of acute cystitis will be cured by a few days in bed, urinary antiseptics and a few irrigations. When the inflammation persists, in spite of these measures, we must look for some other lesion, either in kidney or ureter, in pelvis or urethra, or in the mechanism by which the bladder should be emptied.

In order to test the soundness of this belief, I have collected the histories of ninety-eight women with cystitis. Some of these were ward cases, some outpatients at the Massachusetts General Hospital. All have been seen there within the past five years. These ninety-eight patients comprise all of the cases of cystitis found in the diagnosis catalogue for that period, whether or not occurring in conjunction with other diagnoses. There are also included a few cases of pyonephrosis in which cystitis was present, and ten cases diagnosed as urinary tuberculosis. The last-mentioned were included because the symptoms for the relief of which the patients came to the hospital were those of bladder irritability. No cases of calculus were considered.

Definite evidence of cystitis was required, thereby excluding several cases of "irritable bladder," the urine of which contained neither pus nor bacteria. The process was either seen to exist at cystoscopy, or else was indicated by the symptoms of frequent and burning urination, accompanied by pus or bacteria in the urine. Cases not showing one or the other of these requirements were rejected.

In classifying the cases according to their probable diagnosis, considerable care was observed. In many of the records the evidence was conclusive, as for example, finding the colon bacillus and pus in the urine from ureter catheterization. In others, it was only presumptive, as in a case in which a large, tender kidney, temperature of 102 and colon bacillus from the bladder urine pointed so strongly to pyelitis that there could be no reasonable doubt of the existence of that disorder. In five cases the facts were too inconclusive to admit of any definite diagnosis, and in eleven cases there were too few facts for the record to be of any value whatever.

In eight of the ninety-eight cases there was unilateral pyonephrosis. Two more patients were proved at operation to have focal necrosis. One, at necropsy, showed suppurative nephritis.

In thirty cases the diagnosis was pyelitis or pyelonephritis. In the absence of very careful study, it is impossible to differentiate between these conditions, so that I have grouped these cases together. In sixteen the diagnosis was definitely established by obtaining pus or bacteria, or both, in specimens from the ureter. In one, both ureters were dilated and both kidneys tender; in another, necropsy showed a pyelonephritis. In twelve the diagnosis was based on circumstantial evidence, such as renal pain, fever and a marked albuminuria, accompanied by painful, frequent urination, and pus and bacteria in the urine.

There were five cases of pyelitis in which the evidence pointed more or less directly to an obstruction at the ureteropelvic junction. In one the pelvic capacity was 45 c.c.; in another, 60 c.c.

One case thought to be pyonephrosis proved at operation to be an infected hypernephroma.

Considering this group of forty-one cases of renal infection as a whole, it is an interesting fact that in twenty-nine a bacillus, probably colon, alone was recovered, in two, the colon bacillus plus a diplococcus in one case, a streptococcus in the other. In one case, diplococci and streptococci were found; in another a "mixed growth." In two cases some pus was obtained, but it yielded negative cultures and negative guinea-pigs. In five, no mention of the bacteriology was made. These figures suffice to show the overwhelming predominancy of the colon bacillus in renal infection.

The route by which the kidney is infected has been the subject of much discussion. Two of the pyelitis patients had colon bacilli in the blood as well as in the urine, a phenomenon which may as well have been the result as the cause of their infection.

In five cases there is at least superficial evidence that the trouble began in the bladder and ascended to the kidneys, but here again one may argue that the cystitis was the effect rather than the cause. The fact that renal infection may occur without cystitis, but that cystitis (excluding that due to cystocele, stricture, etc.), never occurs without a renal infection, is in my opinion the most telling bit of evidence against the ascending route.

There were seventeen cases of urinary tuberculosis. In five of these the tubercle bacillus was present in ureteral specimens. In nine more tuberculous kidneys were removed. Another one, with sterile pus in the urine, exhibited a pathologic ureteral orifice. In another patient, whose bladder urine infected a guinea-pig, the right ureteral orifice was of the retracted, golf-hole type. In the third, in which the guinea-pig died too soon for diagnosis, the bladder-pus was sterile and the left ureter pathologic. Every case of tuberculosis showed evidence of renal involvement.

Two patients had cystoceles. One had a pyelitis (colon) as well. The other was cured by perineorrhaphy and a few irrigations.

Three strictures of the urethra were found. Two of these had sterile urine containing no macroscopic pus; one of them, on cystoscopy later, showed a few trigonal ulcerations. Both, however, had marked frequency and pain on urination.

There was one case of ureteral stricture, with a pyelonephritic kidney behind it and great vesical distress, and there was one tabetic bladder. The more acute stage of syphilis was represented by an ulcerative cystitis which cleared up, after obstinately resisting other forms of treatment, on mercury and potassium iodid.

Three cases of cystitis were apparently due to pelvic inflammation. In one, the bladder was adherent to the appendix; in a second, to the uterus; in a third, there was a coexistent acute salpingitis.

In five cases the diagnosis was not made with certainty. The patient in Case 84 gave good evidence of having a stricture of the ureter. In Case 85 there had been cystitis ever since a nephrectomy (cause unknown) eight years before. In Case 86 a subsiding cystitis was shown with slight evidence of a previous pyelitis. The patient in Case 87 had severe renal colic, associated with hematuria. Case 88 was apparently due to mobility of the right kidney, in which a low-grade infection had set in. This patient had a little pus in the urine, from which no bacteria could be grown. She wore a kidney belt, put on 20 pounds in weight, and all the symptoms disappeared.

Eleven cases were so insufficiently studied that no conclusion could be reached.

We have remaining, therefore, eight cases of the ninety-eight in which a simple cystitis was found. The patient in Case 76 was apparently cured by rest in bed for eight days, with hexamethylenamin (*urotropin*) by mouth and a daily silver nitrate lavage. Case 77 showed a red trigon with a few ulcerations. There was no bacilluria and a *negative guinea-pig* inoculation. This patient had a postural defect, with exaggerated knee-jerks, and it is possible that some trophic disturbance might have been the cause of her cystitis. Case 78 was insufficiently studied, inasmuch as the ureters were not catheterized, the cystoscopist relying on the appearance of the ureteral jets. Case 79 was coexistent with a gonococcus urethritis. Cases 81 and 82 were due to continued use of the catheter required by the general condition. Cases 80 and 83 were part of typhoid and paratyphoid infections.

Summary of the eighty-seven cases with *diagnoses shows that cystitis was associated with:*

| | |
|---|---|
| Renal infections, not tuberculous, in | 61 per cent. |
| Renal tuberculosis .. .............. | 19 per cent. |
| Difficulty in emptying bladder...... | 7 per cent. |
| Systemic and pelvic infections...... | 7 per cent. |
| Other causes ...................... | 6 per cent. |

We see, therefore, that in ninety-eight cases there is not one well-studied case of simple cystitis. Every case which was really studied showed a certain or presumptive underlying cause. It cannot be that simple chronic cystitis which is worthy of the name exists with any frequency, or it would, I am sure, have appeared within these records.

The outpatient department attracts often the most trifling ailments; it is hardly possible that it should not have drawn in *a few cases, at least, of simple chronic cystitis, did that* disease exist.

The answer is obvious: it does not exist. It is the duty of the urologist to drive that fact home, and to impress on medical men and the public the necessity of thorough study in every case of persistent inflammation of the bladder.

309 Marlboro Street.

## ABSTRACT OF DISCUSSION

Dr. Bransford Lewis, St. Louis: In the treatment of cystitis we ought to repress as much as possible the idea that cystitis is an original disease and say that there is no treatment for cystitis, except as it is based on a definite recognition of the cause. The more we can affirm that idea the better for progress in urology. I have for a long time followed the policy that, even though I thought the location of an *infection* in the *urinary tract* was in the vesicles or the prostate or the posterior urethra, if I did not make progress, I would do cystoscopy and ureteral catheterization; I have often surprised myself by finding the presence of an infection *in one* or both kidney pelves. It is *often more important* to establish the origin of the infection than just the kind of infecting microbe that is present.

Another point relates to the amount of reliance to be placed in ureteroscopy through the cystoscope. *I do not have much* confidence in *my* own ability in that direction, or in that of others. I had a peculiar case lately *in a girl, 17 years old,* whose right kidney was full of stones, *necessitating* the removal of the kidney, *and on* the other side a certain degree of infected *pyonephrosis without* the presence of stone. I *have* been washing out that kidney pelvis. The question comes *up whether it* would be necessary to *do a nephrotomy* for a more positive drainage, or maybe change the position of the kidney, as suggested by Dr. Fowler.

Dr. O. S. Fowler, Denver: Dr. Smith has not taken into consideration one class of cases in which we see cystitis; that is, cases of cystitis following either pelvic or abdominal operations, especially cases in which catheterization has been resorted to afterward. I have seen a number of these cases, *and they cause* a great deal of trouble. Some of these patients, however, *while not* having been catheterized, do recover after the washing out of the bladder. In those cases it would seem as if the infection did not extend upward, for in a great number of them we do get kidney symptoms. I have had the opportunity of working out some of these cases and have proved that an infection came from the kidney. I should like to ask Dr. Smith what his experience has been in reference to the postoperative catheterization of women.

Dr. W. T. Elam, St. Joseph, Mo.: Unless there is some definite bladder pathology the word "cystitis" is not applicable. In certain nervous conditions there may be urinary symptoms that resemble to some extent a cystitis. The condition is not a cystitis, however; it is merely a neurosis; and it exists not only in women, but also in men.

Dr. Fowler referred to catheter cystitis. We all know that a congestion may exist as a result of catheterization, which may give a *little* irritation and may perhaps result in burning and frequent urination. That is not a cystitis unless there is an infection and a pathologic condition which means inflammatory exudates, serous and cellular. A chronic cystitis, in my judgment, is some chronic change in the bladder walls or mucosa. The doctor's statistics are, beyond all question, of value. If they could have been supported by microscopic examinations of the bladder tissue, thus determining absolutely that there was no disease in the bladder, then we could quickly make the attempt to rule out chronic cystitis. After childbirth and after operation, whether catheterization has been done or not, we have urinary symptoms that often appear to be relieved not only by lavage, but simply by introducing a permanent catheter and draining the bladder; yet we all are willing to admit that bladder irritation may come as a result of pyelonephritis or of pyelitis or an involvement of the upper urinary tract. There are a great many cases apparently of neurosis of the bladder, especially in women.

Dr. M. Krotoszyner, *San Francisco:* I wish to emphasize the importance of expectant treatment, which is apt to yield excellent results in a good *many* cases of cystitis or infection of the bladder. Being well trained in the use of modern instruments, urologists, as a rule, resort too quickly *to* instrumentation, by means of which the patient's untoward symptoms are often intensified. Instrumentation for diagnostic purposes is strictly indicated, however, in all forms of bladder irritability that are not benefited by judicious *local* treatment. In young women particularly the *initial symptoms* of renal tuberculosis may be marked by frequent and painful micturition, and an early diagnosis in these *cases is feasible* only on the basis of careful and repeated cystoscopic examinations.

Dr. J. R. Caulk, St. Louis: I agree *with Dr. Smith* that the great majority of bladder infections are *secondary to* some other influence. I do not believe *strongly* in the neurotic element, the nervous bladders in young women *particularly.* I have seen *any number* of cases in *which patients* have been doomed to a life of neurasthenia as a *result of* this belief, and I think that this section ought *to correct* this impression.

I do *not think* that nerve lesions exist *and cause* distress, but I believe that all these neurotic bladders *have* something back of them. In the great majority of cases sent *to me* with that particular diagnosis I have found *some* lesion in the pelvis—fibroids in the *anterior* wall of the uterus, *or* some lesion in the appendages—and I do not believe *that we* ought to say that a person is suffering from a nervous bladder until we have utilized every means at our disposal to rule out every lesion in the pelvis and upper urinary tract.

**Dr. Thomas M. Paul**, St. Joseph, Mo.: In regard to the manner in which the *Bacillus coli* reaches the kidney or bladder: There is a source of infection which I believe is usually overlooked. In the act of defecating in the modern toilet, as the fecal mass drops into the water there will be a return splash. The first splash may be composed entirely of clear water, but the subsequent splashes, resulting from the continued dropping of fecal masses, will contain many bacteria. While the mucous surface exposed in the male is small, and infection cannot readily take place, in the female it is much larger and contamination of the vulva is sure to occur. If this be true, it is easy to understand how an infection of this kind can ascend through the urethra and cause a cystitis.

**Dr. A. L. Chute**, Boston: The last point is well taken, because these persons are all made better by treatment of the bladder, although the source of the infection is above. The bladder is, of course, improved under lavage; therefore these treatments are given forever. In these cases I think that there is not only an infection of the kidney pelvis, but also a kidney pelvis that does not drain itself. My own belief is that disease of the kidney pelvis in the ordinary person, barring tuberculosis, is cured if there is drainage.

**Dr. G. G. Smith**, Boston: I hoped that this paper would elicit more discussion. I wanted to find out if any of you really have had cases of persistent cystitis in which careful examination showed no source of infection in the kidney or in the mechanism of emptying the bladder, and I must say that although several men have suggested to-day that they have seen such cases of chronic cystitis, no one has mentioned any case which has been thoroughly studied and in which the infection was shown to be residual in the bladder alone.

The criticism was made that in this paper I have considered a number of cases in which true cystitis did not exist. That is not so, because I said, "One of two pieces of evidence was required; either the bladder was seen to be inflamed at cystoscopy, or pus and bacteria were found in the urine."

I have not seen much of the cystitis which follows operation on women. It seems to me that what usually happens is that the woman is allowed to go without urinating until her bladder becomes much distended and then she is catheterized. As we know, catheterization always induces hyperemia, and, as has been shown by the men I quoted, the colon bacillus is present in the urine in twenty-four out of twenty-six women after operation. The bladder is congested by being suddenly emptied, and it becomes infected. Thus you do have a cystitis in these cases, but it clears up under a comparatively simple line of treatment. If it does not do so the infection is found to be seated in the kidney.

I am glad that Dr. Chute brought up the point that bladder lavage will help in these cases of renal infection, because that is true. I have in mind now a patient who was benefited by lavage as long as she kept it up. I grew colon bacilli from both kidneys, and found pus in the urine from both kidneys. Yet she came for bladder lavage because it made her feel better. Infection by the use of toilets does not seem probable for this reason: If cystitis occurred from that we should more often see a pure cystitis without kidney involvement. It seems to me that a strong point in favor of the descending route is the fact that, whereas you may find a pyelitis without a cystitis, you rarely, if ever, find a cystitis without a pyelitis.

---

Recruits for the Army.—Great difficulty is experienced by the War Department in securing a sufficient number of suitable recruits to fill existing vacancies, on account of the mental and physical degeneracy of the young men who present themselves for examination. During the year of 1912 only 35,837 recruits were accepted from 159,673 applicants examined, a rejection of 76 per cent.—L. M. Mervin Maus, in *Chicago Med. Recorder.*

# THE PREPARATION OF PRIVATE HOUSES FOR OPERATIONS

JOHN COOKE HIRST, M.D.
*Associate in Obstetrics, University of Pennsylvania*
PHILADELPHIA

It is perfectly feasible to arrange private houses for operations so that the lack of hospital facilities need not be felt. An abdominal operation is, of course, more easily done and the patient more easily cared for in a hospital than at the patient's home, but even this type of operation can be adequately cared for at home, provided the preparation is sufficiently well made. Ordinary operations, especially plastics for the repair of the injuries of childbirth, are satisfactorily done in the patient's home. A trained nurse, or one at least accustomed to the care of surgical cases and with a working knowledge of asepsis, is most desirable, but not indispensable, provided the physician is willing to give minute instructions as to the care required and to attend to such details as catheterization himself.

*The Choice of a Room.*—If possible, the room should be one adjoining the patient's bedroom, and preferably not the patient's own room. The patient is thus spared the sight of the necessary preparation. The paramount question is one of light, and the operating-table should be so placed as to get the maximum amount, hence, near the window. The window can be screened against outside observation by covering it with a single piece of gauze or by pinning together the curtains, provided they are of a material which will transmit the light without too much diminution, or even by soaping or whitewashing the pane of glass. Except for an abdominal operation it is not necessary to strip the room or take up the carpets or rugs. The floor can be protected by newspapers, thickly laid, and over these a sheet, wrung out of a 1:1,000 bichlorid solution, should be spread and should be damp when the operation is begun. Any unnecessary hangings ought to be removed and the furniture moved to a part of the room where it will be out of the way and covered with sheets. The walls in the immediate vicinity of the operating-table should be protected by sheets held up by the glass-headed pins known as Moore's push-pins, and not by tacks. The pins leave no scars, as tacks do, especially in wall-paper and plaster.

*The Operating-Table.*—This should preferably be one of the models of portable, collapsible operating-tables, but this is by no means a necessity. A kitchen table with sufficient strength of legs answers every purpose. If this is used, the top must be thoroughly scrubbed and then thickly padded, as the thinly padded table is a prolific cause of backache after operations. In many operations, notably perineal operations, a Kelly pad is a most desirable addition; but one that will answer every purpose can be improvised by rolling up rubber sheeting at the sides and back, or even newspapers covered by towels or sheets. The special tables are provided with stirrups and leg-holders for the lithotomy position, when this position is desired. The kitchen table can be equally well equipped with either the Edebohls portable leg-support, which clamp on the edge of the table, or, much better, by a rolled sheet tied about one knee, passed back over one shoulder and out under the other (so that pressure does not come altogether on the patient's neck) and fastened above the other knee. The knots should be on the outside of the leg. This makes the best leg-holder I know. If the Edebohls supports are used, it will be found necessary to tighten the screws with a wrench (no one's fingers are strong enough), for, if the patient should strain, the leverage is enormous. If a chair or stool is needed, a piano-stool draped with a sheet is most satisfactory, but a plain chair (not too low) will answer. The end of the Kelly pad, or its substitute, should drain into a bucket or slop-jar which has been well scalded out.

The special operating-tables have apparatus for the Trendelenburg position; the kitchen table can be equally well equipped by raising the two legs on blocks or bricks, or even, if the extreme position is desired, on the seats of two chairs. The whole table is best draped in a sheet, although this is not essential.

*Instrument- and Dressing-Tables.*—Two of these are required, one on either side of the operating-table. As these tables often have polished tops, adequate protection must be provided. This is best done by covering the top thickly with newspapers, placing on these a large tin tray and covering all with a sheet, draped so that it will touch the floor on all sides. This is to protect the legs and sides.

*Douche-Bag.*—This is needed in all perineal operations, and a more efficient means of splashing the wall-paper than an improperly hung douche-bag can hardly be devised. A suitable hook is provided, preferably in the window-frame. An open towel is placed over this hook so that the center of the towel is over the hook. The bag is hung on the hook and the towel allowed to drape down over it. This has proved an adequate protection. The douche-bag and tube are, of course, prepared by boiling.

*Instruments.*—It is best to boil these where the physician and nurse can keep an eye on them. A large alcohol lamp and a copper tray sterilizer or basin will be satisfactory. If an alcohol lamp is placed in the bathtub, and the instruments are sterilized there, it will guard against the danger of upsetting them and possibly a conflagration. If the instruments are sterilized over the kitchen stove, servants must be warned not to touch them. I have seen a servant dig the various instruments out of the sterilizer with a stove-lid lifter and speculate on their uses.

*Dressings.*—For all ordinary operations the commercially sterilized gauze and cotton are entirely satisfactory. For abdominal operations the dressings should preferably be steam sterilized either in an autoclave or even in a Rochester steam sterilizer. If the latter is used, the final sterilization should be completed just before the operation. It is not possible adequately to dry dressings so sterilized, and it is better to have them warm and wet than cold and clammy. Sheets and towels can be adequately prepared by freshly laundering them and then ironing with an iron hot enough to come just short of scorching them. The time-honored custom of baking in the oven of the kitchen range is useless. Such dressings are not sterile unless so scorched as to be unfit for use. For gauze sponges, I have always found the commercially sterilized gauze safe. If sea sponges are used, they must be soaked over night in a 1:500 bichlorid or a 1:20 phenol (carbolic acid) solution. Boiling them destroys their absorptive qualities.

*Basins.*—Unless the physician carries his own nest of basins, he must depend on the household supply. Three at least are needed and they must be boiled. Rinsing or wiping them out with an antiseptic solution is not sufficient.

*Scrubbing.*—The best arrangement for scrubbing up and sterilizing the hands can be made in the bath-room. Running water and previously boiled nail-brushes are used, and to obviate stooping over, the dishes of soap, alcohol, etc., can be arranged on a bread-board placed over one end of the tub and resting on the sides of the tub.

*Rubber Gloves.*—Steam sterilized and, hence, dry gloves are best, but this is not always practicable. Boiling is a method always available and is satisfactory. The gloves must be boiled wrapped in gauze or a towel, and should always be boiled flat so that the water can enter them. The custom of boiling gloves rolled up in a ball is a pernicious one, as the inside of these gloves is never sterile and most of the outside is open to grave suspicion.

*Sterile Water.*—The night before operation a clothes-boiler is filled with water. In it are placed three pitchers and a dipper with a hooked handle. These are boiled for half an hour. The pitchers are hooked out of the water with the handle of the dipper and filled, and then towels are tied over their tops and they are set aside to cool over night. The next morning the clothes-boiler full of water and the dipper are boiled again. Thus by mixing the cold water that has stood over night with the hot water boiled just before the operation a supply ample for most operations is secured.

In emergencies, the bottled water sold at all drug-stores is adequate for the cold sterile water, except in abdominal operations. The water in the pitchers can be cooled in a reasonably short time by pouring cold water over the outside of the pitchers.

*Supplies Required.*—The supplies needed for an ordinary operation are as follows: six sheets; twelve towels; 8 ounces of 95 per cent. alcohol; 8 ounces tincture of green soap; 1 pound of absorbent cotton (two half-pound rolls); one 5-yard roll of sterile gauze; one 1-yard jar of iodoform gauze; one bottle of mercuric chlorid tablets; one 2-ounce bottle of pure glycerol (glycerin, as a lubricant for putting on wet gloves); two ½-pound cans of ether, unopened; three small coarse (not silk) sponges, size of orange; one 1-yard package of sterile gauze (for the etherizer, to avoid opening the larger package).

I have this list printed on cards, and one is sent to the patient's house to guard against details being forgotten.

*Nurse's Kit.*—I find it useful to provide the nurse who does all the preparing of houses for me with a bag equipped with what we have found needful. This bag is small and easily carried, but contains nine basins, twelve brushes, twelve pairs of rubber gloves; all the catgut used in the operation (from eight to ten boxes being carried); a Kelly pad; douche-bag; razor for shaving patients (especially in perineal operations); gown and uniform; the glass pins (3 dozen) used for protective sheets, and a roll of safety-pins.

It is perhaps unnecessary to point out that all visible disturbances caused by these preparations should be cleared away, and all soiled linen and sponges and water disposed of as soon as possible. This is particularly desirable when everything has been prepared in the patient's room. No signs should be left for the patient to see on recovery from the anesthetic.

1823 Pine Street.

So are there some vain persons that whatsoever goeth alone, or moveth upon greater means, if they have never so little hand in it, they think it is they who carry it."—*Bacon.* Remedy: "Nothing can be better adapted to turn man's thoughts off his own self-sufficiency than the works of Nature."—Maund, *Pub. Health Jour.*

# A CASE OF SYSTEMIC BLASTOMYCOSIS

ROBERT T. MORRIS, M.D.
Professor of Surgery, New York Postgraduate Medical School and Hospital
NEW YORK

*History.*—Dr. B. H. A., aged 37, Brownwood, Tex., was admitted to the Post-Graduate Hospital, Feb. 28, 1913. Family history and personal history have no important bearing in the report, but points in past history may be mentioned. The patient suffered from "malaria" for several months when a young child, but did not remember any other illness. At the age of 18 he suffered from what was probably acute appendicitis, but was not operated on. For the past eight or ten years the patient has usually had a severe cold every winter, coughing for about a fortnight and then recovering. During the winter of 1911-1912 he coughed nearly all winter. The sputum was mucopurulent and scanty never bloody or with odor.

*Present Illness.*—This dated from November, 1912. The patient went from Texas to Chicago and engaged in postgraduate medical work, including necropsies and dissections. Soon after arrival in Chicago, he had a "cold" with coryza, severe cough and scanty mucopurulent sputum. The cough continued up to the time of death and was most marked at night. The sputum was tenacious, mucopurulent, odorless and never bloody until a few days before his death. Shortly after the onset of this cough the patient began to complain of pain in various joints, involving one at a time; first the right knee, then the left shoulder, then the right shoulder, lasting altogether about two months; none of the joints became red or swollen. The patient continued his medical studies. During this period he had a slight fever most of the time, rectal temperature ranging from 100 to 101 F. in the evening. While in Chicago the patient developed a pustule on the left index-finger which did not heal, and there remained a small indurated area covered with a scale or crust which spread from time to time and discharged a trifle occasionally. This area had never been painful or swollen.

Jan. 1, 1913, the patient sailed for Liverpool. During the journey he suffered from pain in the right chest on deep breathing, not very severe or sharply localized. January 8, he was suddenly seized with severe stabbing pain in the right lower chest posteriorly. Deep breathing accentuated this pain. The patient had irregular rigors and high temperature. He entered a London hospital, where a roentgenogram was taken of the chest and abdomen. In consultation with authorities in London it was decided that he was suffering from a liver abscess.

*First Operation and Results.*—January 15 an operation was performed. Incision was made over the ninth rib posteriorly. No pus was found with the aspirating needle in the liver or pleural cavity. The ninth rib was found to be necrotic for several inches near the point at which examination was made, and the necrotic portion was removed. The sinus has never healed, but has continued to discharge a thin yellowish or brownish fluid in small quantities (there had never been jaundice).

Following the operation, the patient had intermittent fever varying from 99 F. in the morning to 105 F. in the afternoon, with profuse sweating. This type of fever continued. The patient developed the morphin habit on account of severe pain in the right chest. Blood-count made in London was said to be negative. Several small abscesses appeared on the chest and lower extremities, cultures from which are reported to have been negative.

February 22 the patient sailed for New York, arriving on February 28, when he came immediately under my care. During the voyage he developed severe pain along the course of the right sciatic nerve and also a lumbago. This feature caused great distress at the time of his admission to the hospital. Dr. McPhee, who examined the patient at my request, reported finding irritation of the right sciatic nerve, the cause for which he could not determine. Dr. Lattin found, on lung examination, numerous coarse and fine moist râles over the left base posteriorly from the fifth rib down. About the angle of the left scapula there was bronchovesicular breathing. Percussion note was slightly impaired over this region. Breathing sounds were obscured by râles. Over the base of the right lung, below the angle of the scapula, were scattered subcrepitant râles. Under my direction systematic examination was made of the blood and of the excreta. There was no leukocytosis. Two blood-cultures gave negative results. Urine examination was negative. Sputum examination was negative for tubercle bacilli. Von Pirquet test was negative. Wassermann test was negative.

March 22 the patient complained of sudden sharp pain in the right lower chest, especially on deep breathing. This gradually subsided in a few hours. Examination at this time showed a few subcrepitant râles in the right lower axillary region. Breathing sounds were clear. The edge of the right lobe of the liver extended a little below the costal margin, but was not tender. There was marked tenderness on pressure, however, over a large part of the right lobe of the liver. The spleen was not palpable. The patient was fairly well nourished and partook of nourishment sparingly. He was irritable but fully rational during the days shortly after his admission to the hospital, but irrational, at times, later. The tongue and lips were moist and of natural color. The skin seemed ashy, and this ashiness increased as the illness progressed. There was progressive weakness and emaciation, which did not, however, become extreme. Several physicians and surgeons who were asked to see the patient in consultation did not arrive at a satisfactory diagnosis. Roentgenoscopy showed a tendency to consolidation at the bases of both lungs and a moderate degree of enlargement of the liver, marked more by arching of the diaphragm than by extension of the sharp edge of the liver below the costal border. It was my feeling that we were dealing with subphrenic abscess or with abscess of the cephalad portion of the right lobe of the liver, and that the lung consolidation represented an infection by way of lymph-vessels of the diaphragm; although some of the consultants believed the case to be one of bronchopneumonia with lung abscess, based on the physical signs and the roentgenogram, which showed that from the hilum of the lung on the right side, extending outward in the parenchyma, there was an area of diffuse inflammatory invasion.

*Later Operations and Course.*—On the basis of my feeling that we were dealing with subphrenic abscess or hepatic abscess, the patient was anesthetized, March 26, and an aspirating needle passed in several directions in a search for pus, including the subdiaphragmatic region and also penetrating the diaphragm to the pleural cavity; but no pus was found. The patient suffered very little from the operation.

April 12, after further consultation, it was decided to make a small incision at the lower right costal margin for the purpose of searching for an abscess which might appear on palpation of the liver. No abscess was found on palpation, and a long steel sound passed freely over the dorsum of the liver discovered no area of adhesions, excepting at the site of the London rib excision. There were extensive adhesions, however, about the gall-bladder and the lower margin of the liver to adjacent viscera. These adhesions were separated by sweeping the finger about, and the gall-bladder was felt to be distended. It was not thought best to enlarge this incision for the purpose of draining the gall-bladder at that time, as it seemed desirable to be satisfied with the results of quick exploration.

The patient suffered little from this operation and on April 19 another small incision was made and the gall-bladder drained, in the belief—based on the extensive adhesions in the vicinity—that we might have a collection of pus in the gall-bladder. The gall-bladder, however, contained nothing but a large amount of mucus colored with bile. This operation, like the others, disturbed the patient little, as it was quickly done, but it yielded no result. The patient continued to fail gradually, notwithstanding the application of various general resources for maintaining his strength. Superficial abscesses occasionally appeared on the chest and legs. These abscesses would develop quickly, without redness or induration, and with barely enough pain to attract the attention of the patient, and when evacuated were found to contain a thin yellowish or brownish pus. There was one abscess on the forehead, at the margin of the hair.

May 4 one of the staff men, Dr. Hjelm, obtained a culture of blastomyces from a small abscess of the neck, and a pure culture having been obtained later, the case was definitely determined to be one of systemic blastomycosis. The sputum had been carefully examined, but on account of the number of cocci and bacilli (with the staphylococci predominating) it had been difficult to obtain a culture separating the blastomyces.

The diagnosis of systemic blastomycosis having been established, attention was given to the small scaly area of the left index-finger, which had been considered of little consequence. Dr. Pollitzer, who examined it, decided that it was a small area of blastomycosis of the skin. The patient, on being questioned, stated that he had pricked himself at this point while dissecting in Chicago in November, 1912.

After the diagnosis was established, potassium iodid was given, but this was not borne well and was dropped, my belief being that it is efficient only when we have the skin lesions of blastomycosis, because of the selective action of the glands of the skin in excreting potassium iodid. An examination of statistics seemed to show that it had not been of value in case of systemic blastomycosis.

An intravenous injection of neosalvarsan was given twice, but to this the patient made no response of consequence. A culture of the blastomyces was being developed for the purpose of preparing a vaccine, but before we could employ this the patient died, May 11, from general exhaustion, the last record of vital signs showing a temperature of 102 degrees F., pulse 166, respiration 10.

The patient at that time had been hiccoughing at frequent intervals and tried at many times to vomit, bringing up small quantities of greenish mucus.

Post-mortem examination was not permitted.

*Characteristic Blood Examination.*—March 2: Leukocytes 10,500, polynuclears 79 per cent., and lymphocytes 21 per cent. The hemoglobin, which was 90 per cent. at the time of the patient's entrance to the hospital, had dropped down to 70 per cent. on April 11. Blood examinations were at all times negative.

*Sputum Examination.*—Various cocci and bacilli were found, staphylococci predominating.

*Characteristic Urine Examination.*—March: reaction, acid; color, amber; specific gravity, 1.015; albumin, none; sugar, none; calcium oxalate crystals. Characteristic urine examination in April: reaction, acid; color, orange; specific gravity, 1.020; albumin, negative; sugar, negative; amorphous urates.

*Characteristic Rectal Temperature.*—From the time of his entrance, February 28, until April 15: Morning temperature varied from normal to 101; evening temperature, from 104 to 105. There was occasional subnormal temperature to 97. After April 15 there was much less variation between morning temperatures, probably because of decreased strength of the patient, and the characteristic temperatures ranged between normal and 102 until May 3, after which the temperature remained not far from normal, with a tendency to become subnormal, from 97 to 98, until the time of his death.

*Characteristic Pulse-Rate.*—This followed the temperature in an ordinary way until April 15, ranging between 100 and 138; the respiration rate ranged from 24 to 28 during this time. After April 15 there was little change in the respiration-rate; pulse-rate varied from 100 to 128. After May 3, respiration-rate ranged from 18 to 26 and the pulse-rate from 100 to 152.

For ten hours preceding death the temperature steadily rose to 102, pulse-rate ranged from 148 to 166 and respiration remained at 10.

It is probable that systemic blastomycosis is not a particularly rare disease, but the diagnosis is not often made. The number of cases reported from Chicago means presumably that Chicago physicians make the diagnosis more readily than it is made elsewhere.

616 Madison Avenue.

# NOTE ON A MOLD, COCCIDIOIDES IMMITIS, FOUND IN A CASE OF GENERALIZED INFECTION IN MAN

WARD J. MacNEAL, Ph.D., M.D.
Professor of Pathology and Bacteriology, New York Post-Graduate Medical School and Hospital
AND
C. E. HJELM, M.D.
Intern in Bacteriological Laboratory, New York Post-Graduate Medical School and Hospital
NEW YORK

A sample of pus, obtained by incision of a subcutaneous abscess in the case reported by Dr. Morris in this issue of The Journal, was sent to the laboratory for examination on April 23, 1913, Laboratory No. 8511. Microscopic examination of stained preparations of the pus was negative. Plate cultures on ascitic-fluid agar brought to development, after incubation for forty-eight hours, numerous colonies of radiating mycelial threads and a very few bacterial colonies. The appearance of the colonies suggested the possibility of oidiomycosis.

The patient was seen by us on April 25 at the invitation of, and in consultation with, Dr. B. Lattin. The clinical condition of the patient, as well as the history of the illness, was found to be quite in accord with the indication of the laboratory examination. At this time a second specimen of pus was obtained from a closed subcutaneous abscess by aspiration into a clean sterile syringe.

*Microscopic examination* of this pus suspended in salt solution revealed numerous doubly contoured colorless spheres, varying in diameter from 4 to 25 microns. The larger ones were distinctly granular and filled with rather faintly visible globular bodies varying from 1 micron to 5 microns in diameter. Some of the larger spheres were found ruptured with the small spheres evidently ready to escape from their interior. No budding forms or mycelial threads were recognized in the pus.

On the plate cultures of this second specimen of pus many colonies of mold developed, apparently in pure culture. Each colony consisted of a mass of radiating, interlacing, branched and septate threads, surrounding the remains of a spherical body at the center, from which the colony evidently originated.

The organism is regarded as identical with that discovered by Posada and Wernicke,[1] and first described in the United States by Rixford[2] in two cases, and subsequently studied by Rixford and Gilchrist,[3] who bestowed on it the name *Coccidioides immitis.* The work of Ophüls and Moffit[4] and of Wolbach[5] has established the classification of the parasite as a mold. The specific name *Coccidioides immitis* (Rixford and Gilchrist, 1895), should nevertheless be retained, unless a more complete knowledge of the organism shall finally determine its position in some prior genus of the fungi.

Twentieth Street and Second Avenue.

# SOME INTRA-ABDOMINAL COMPLICATIONS FOLLOWING LAPAROTOMIES *

ARTHUR E. BENJAMIN, M.D.
MINNEAPOLIS

Some of the questions that a patient who is suffering from abdominal disease considers before an operation is consented to are:

1. Has a proper diagnosis been made in his individual case?
2. Will the operation cure him of his trouble?
3. Will it leave him in a worse condition?
4. Will it leave a different train of symptoms with an equal amount of suffering?
5. Is the disease of such importance that he is warranted in taking the risk of an operation?

For a number of years I have been investigating the cause of postoperative intra-abdominal disturbances in my own as well as other surgeons' cases that have come to my attention, and have tried to determine the underlying factors in the production of the various symptoms that patients complain of after laparotomy.

Intra-abdominal pain is usually due to some interference with the function of the alimentary canal, and this may be because of acute or chronic inflammation of the peritoneum, which inhibits peristaltic action of the bowel, or to obstruction of a more chronic nature due to bands, kinks and flexures of the various portions of the digestive tract, producing stasis, resulting in retained food, mucus and gas.

When it is possible for the contents of the stomach to pass readily from the stomach through the pylorus, duodenum, small intestines and colon in the required amount of time for digestion, assimilation and elimination of waste products, the patient experiences no particular discomfort; but, if this period is prolonged, decomposition of semidigested food, distention from retained waste products, gas and mucus often result. The patient suffers from local pain, general disturbances and systemic intoxication.

## THOROUGHNESS OF THE OPERATION

Associated lesions other than the one especially for which an operation is performed may be equally responsible for the patient's suffering. When a laparotomy is performed it is incumbent on the operator to investigate all abdominal and pelvic organs within his reach to determine if this is the case or not. According to Bottomley, "An attempt should be made to find adequate pathologic cause for the patient's symptoms."

It is essential indeed that the surgeon determine if the function of the stomach or intestines is so interfered with as to modify results. The operative technic and thoroughness of the operation have much to do with the comfort and well-being of the patient after the operation. The carefulness of the work and the method of closing the peritoneum and abdominal wall determine to a great extent whether or not the patient remains well thereafter.

## PREEXISTING DERANGEMENT OF THE FUNCTIONS OF THE ALIMENTARY CANAL

In a paper read before the Western Surgical Association, April 10, 1909, on "Chronic Dilatation and Prolapse of the Stomach," I demonstrated the importance of this condition in relation to abdominal surgery I especially emphasized the fact that a stomach which is much dilated or prolapsed works less perfectly and causes much more distress following operations because of retained contents than one of the normal size and in normal position.

Recently I have had several cases in which chronic dilatation and prolapse of the stomach existed, and it was predicted at the time that these patients would have much postoperative disturbance, such as nausea, vomiting and distention. This was verified in nearly all instances. In operative cases having no enlargement or prolapse of the stomach there was less postoperative pain and often no vomiting or distention.

In persons who had previously been operated on for other troubles, with much discomfort following, and in whom there was found a badly prolapsed and dilated stomach, causing such impairment of functions that it was deemed necessary to do something specifically for this dilatation or prolapse, when the stomach was suspended in the proper position by operation little or no postoperative gastric disturbance arose.

Thorkild Rovsing has given sufficient evidence of the importance of a prolapsed stomach and colon and reports sixty-three personal cases in which operation was performed, with 50 per cent. of positive cures and 75 per cent. of cures and improvements.

If we have any adhesions around the pylorus which interfere with the normal emptying of the stomach at the proper time, there may result a distention of this organ followed by nausea, vomiting and regurgitation of bile. A distended stomach interferes with the large and small bowel action. Kinks may be produced and fecal substance and gas trapped within isolated loops. A greatly enlarged cecum with much accumulation of mucus, infectious material and gas further adds to the distention.

Intracolonic tension produces a thinned-out atonic wall which is of less protection to the outlying serosa from infection within. There is a transmigration of the infectious micro-organisms through the thin walls and local infection of the endothelium may result.

The general intra-abdominal tension forces the coils of the intestines in close contact, and in the presence of infection or any raw or denuded surfaces adhesions necessarily follow which may be temporary or permanent according to the variety of the infection, the amount of pressure and the tissue involved. The same rule as applied to joints by Murphy holds in diseases of the abdominal cavity.

## MUCOUS COLITIS AND MEMBRANOUS PERICOLITIS

In cases of mucous colitis I have found that a thorough irrigation of the colon either in the knee-chest position, elevated hip position and right-sided flank position, materially lessens the intra-abdominal postoperative distress

This is especially emphasized when associated with that class of cases known as a membranous pericolitis, in which the operator has been compelled to separate bands of adhesions or liberate the transverse colon that has become fixed to the ascending colon. In such patients the postoperative management and subsequent treatment is important indeed, and determines to a great extent whether we bring about a better or worse condition of the patient.

I know of no class of cases in which the ingenuity of the operator is more put to the test than in this variety, as without question they are the large majority of cases that give the surgeon the most trouble following surgical work. They are the class in which frequently

---

* Read before the St. Louis County Medical Society, Duluth, Minn., June 10, 1913.

the appendix alone has been removed with little or no benefit.

Postoperative adhesions are increased rather than eliminated in such cases if incomplete surgery has been performed. If the constricting bands are not separated the colon functionates imperfectly, the kinks remain, postoperative stasis and tension become quite pronounced and the suffering severe. Retained infectious micro-organisms are forced through the thin colonic walls, often producing local peritonitis with an aggravation of the membranous pericolitis.

### STATE OF THE MUSCLE TONE OF THE ABDOMINAL WALL

Persons with lax pendulous abdominal walls with little or no tone or strength to maintain the normal and proper function of the within contained intestines are liable to have inactivity of the intestines following an operation. There must be in the normal person elastic tone and tension of the abdominal muscles to facilitate the proper propelling of contents and the evacuation of waste products. If this force is wanting, the functions of the intestines and stomach are imperfect and distention, fermentation and intra-abdominal tension often result.

The strength of the abdominal muscles in suitable cases should be developed as much as possible before the operation and a substitute employed temporarily for this tone directly following the operation and further treatment continued thereafter.

### CHARACTER OF INFECTION

So long as an infection of any nature remains present within the abdomen and there is a destruction of the endothelial cells, adhesions occur, and unless the operation favors the elimination of the infection or inhibits the action of the micro-organisms it is of little or no benefit.

The operator should determine the nature of the infection in the given case. If it is of a streptococci type the aim and desire should be to remove the infectious material as thoroughly as possible; then we may expect almost perfect results and few, if any, subsequent adhesions. The same may be true in an infection from colon bacilli, but in tuberculous or gonorrheal infections it is often so impossible to remove the diseased tissue and infectious micro-organisms that we must give a less favorable prognosis.

Adhesions may have been separated at the time for various reasons, such as the removal of a diseased appendix, tube or cystic ovary, but they will recur in some instances and remain until the patient either succumbs or recovers from a general infection. In gonorrhea we may have a few adhesions contiguous to the part removed, as in the stump of a tube, but by careful systematic work we are able to eliminate this possibility to a great extent by taking out the cornual portion of the uterus and carefully covering the stump with the healthier uterine tissue and peritoneum.

### RAW SURFACES OR DENUDED AREAS LEFT WITHIN THE ABDOMEN AFTER OPERATION

Maurice Richardson expressed a belief that raw or denuded surfaces within the abdomen are the most frequent sources of intra-abdominal adhesions. Owing to the increased intra-abdominal tension following an operation, raw surfaces should be obviated as much as possible, and as little traumatism produced as is consistent with a thorough investigation and treatment of the affected tissue.

Every surgeon should be especially careful not to leave surfaces not enveloped with normal peritoneum exposed to contiguous coils of intestines. Exposed suture lines should be as few as possible within the abdomen.

All surgical work done on the female pelvic organs should be so carefully performed that little or no denuded or wounded serous membrane remains within the abdomen or exposed suture lines.

Tubes should be removed so completely and carefully, approximating the serous membrane above the stump and broad ligament wound with plain catgut, that there will be slight chance for loops of intestines or omentum to become fixed thereto. This same rule should apply in doing hysterectomies and in enucleating uterine fibroids, and in the removal of cysts of the ovaries or resection of them fine plain catgut alone should be used to approximate the parts, as this absorbs early. We should be especially careful if more or less infected tissue remains at or near the point of the suture line.

In stomach, intestinal and gall-bladder surgery there is more or less soiling of the serous covering, and if any exposed denuded surface remains, it should be surrounded with omental tissue when suitable and possible.

If there is an unavoidable denuded surface left, detached omental grafts are in most instances best employed. They are preferable to such material as gutta-percha, silver foil, rubber, silk, Cargile membrane, petrolatum, etc.

When an actual cautery can be employed to a raw surface, there is less likelihood of adhesions from deep cauterization, for when the scab separates there is usually a healthy membrane beneath.

### REMOVAL OF APPENDIX

A number of operators are content, in ligating the stump of the appendix, to leave it exposed within the abdomen. It seems to me that this invites adhesions thereto, as we all know that the stump of an appendix has more or less infectious material within its lumen and that it must become fixed, at least temporarily, in some way or Nature must envelop this infectious material with some tissue or exudate.

I believe that there is little call for silk or Pagenstecher thread in appendiceal operations, and it may be eliminated in many other operations in which it is employed at the present day. A non-absorbable suture acts as an irritant, increasing the amount of exudate around the suture to which adhesions can and do occur. By ligating the stump of the appendix with plain catgut, cauterizing and inverting the stump, and by employing a chromic catgut purse-string suture, we accomplish all that is desired and prevent possible adhesions at this point. A number of patients have been reoperated on in which silk or Pagenstecher thread had been used, especially when used in the infected cases.

### OPERATIVE TRAUMATISM

It is surprising the amount of abuse the peritoneum will endure and recover therefrom. Surgeons who operate with bare hands or wear linen gloves no doubt injure the serosa of the intestines to a great extent by nail wounds, pressure or rubbing of the linen gloves.

The amount of traumatism and areas of denudation produced by sponges and gauze packs within the abdomen is hard to estimate. The coils of the intestines are frequently caught between the folds of gauze in endeavoring to push them out of the field of operation and are so severely injured that it is no wonder that postoperative discomfort results from ileus kinks, stasis and adhesions, at least of a temporary nature, from undue pressure, traumatism and denudation of their serous covering.

Injury to the peritoneum by sharp unsuitable retractors, artery forceps and other instruments is not uncommon.

The use of a rubber dam if there is much intra-abdominal tension may, in some instances, be called for: the surgeon should at least place the patient in such a position as to have the intestines gravitate to a point away from the field of operation and carefully and systematically hold them back with moist rolls of gauze and not necessarily crowd them roughly away from the field of operation so as to produce injury of their serous covering.

All unnecessary wounds of the visceral and parietal peritoneum should be avoided, as to these areas omental adhesions are wont to occur or coils of intestines to unite.

### UNDUE EXPOSURE OF THE VISCERA

Prolonged exposure of many loops of intestines without the abdominal cavity to cold air and extra abdominal pressure, as well as unclean skin and wound surfaces, is wrong. A portion of the circulation of these loops may be temporarily arrested with a thrombosis of some of the blood-vessels, all of which may invite postoperative ileus, intra-abdominal tension, infected peritonitis, obstruction and adhesions.

### FOREIGN SUBSTANCES

Inadvertently leaving gauze or instruments in the abdomen are unfortunate accidents and are not infrequent sources of postoperative discomfort and pronounced adhesions.

As soon as the abdomen is opened only large pads should be used to sponge out the abdomen and large three-yard-long wet rollers of gauze used to coffer-dam the field of operation. By this plan I am sure fewer of these accidents will occur.

### DRAINAGE

The subject of drainage is a large one, on which a great deal of discussion has taken place. I long ago formulated a few simple rules which have not varied much in years. If there is a great deal of bloody exudate in an operative field within the abdomen, rubber-tube drainage with fixed or collapsible walls is utilized only so long as there remains an undue amount of discharge, usually for about forty-eight hours, when drainage is removed. Blood makes a suitable medium in which infectious micro-organisms develop. An increased amount of retained blood results in an increased area of infection or organized exudate and adhesions. The early removal of this exudate lessens the area involved and the number of adhesions following.

Septic areas are drained likewise, but for a longer time, until a channel has formed through which this exudate or infectious material may escape. Gauze drainage is seldom if ever indicated, as it drains only for a short time and becomes glued to contiguous tissues, and this gauze, on removal, separates the endothelium from the intestines or inner surface of the abdominal wall, leaving denuded areas which favor further infection and adhesions.

Drainage is established so as best to favor the exit of the discharge and no undue pressure is allowed on the abdominal viscera by drainage material, the patient being placed in a position most favorable for drainage, often laying over on the abdomen.

### CLOSURE OF THE PERITONEUM AND ABDOMINAL WALL

From secondary operations performed on cases previously subjected to laparotomies, we are convinced that the adhesions of the omentum and intestine to the suture line utilized for closing the peritoneal opening are far too frequent. Patients suffer so often with a dragging or pulling sensation at this point with such tension on the transverse colon and stomach that there is an interference with their normal function. Cramp-like pains, nausea, vomiting and stagnant stomach and bowel contents frequently occur, due to a kinking of the pylorus or colon on account of this pull. Surgeons have been generally satisfied to stitch up the peritoneum with an over-and-over running suture of catgut, and have allowed this to suffice even though there may be quite large holes left in the peritoneum through which the omentum may protrude or become attached to the tissue outside of these openings.

Operators often overlook the presence of the fascia layer back of the recti in closing median incisions. This tissue is often allowed to retract and is not brought to the median line with the peritoneum. The peritoneum alone is so thin in many instances that it will scarcely hold the suture when any tension is put on it. This tissue should be included with the peritoneal suture and will lend material support thereto and often prevent postoperative hernia. It is important that the needle does not penetrate the visceral peritoneum or omentum, as temporary or permanent fixation of the tissues so caught may result and much discomfort, or even obstruction of the bowel, occur.

I have also endeavored to pass the suture in such a manner as to have the healthy serous membrane in close apposition to the opposite side by passing the suture back and forth; this is a running Halstead suture according to the Murphy method. This plan gives a less suture-surface exposure and minimizes the raw places within the abdomen.

Direct muscle and fascial approximation are important in closing the abdomen. A running stitch of chromic catgut, including the fascia and muscle, alternately with a stitch including fascia alone, makes a careful approximation. I have followed this method for a number of years and have had very satisfactory results where drainage due to abscess was not necessarily established. Postoperative hernia is so often followed by impaired bowel function and by adhesions with so much suffering that it should never occur in clean cases.

### POSTOPERATIVE MANAGEMENT OF THE CASE

If intra-abdominal tension is one of the factors in the production of postoperative distress and danger, we should consider all elements in the production of this tension and prevent or eliminate them early. First and most important is acute gastric dilatation. In such cases the stomach-tube should be used as soon as much gastric distention is recognized and before any amount of distress has been experienced, especially in cases in which a chronically enlarged or prolapsed stomach has been observed.

This procedure will prevent many cases of so-called postoperative peritonitis and heart weakness. It will save many lives and go a long way toward preventing the adhesions which follow in the wake of operations.

Surgeons are more neglectful of the kind and amount of food and drink that their patients receive after operations than they should be. Few patients with stomach disturbances can stand the carbohydrates; these often cause distress and distention. Such patients do not endure cold drinks well. Hot alkaline aqueous solutions and hot liquid food are best tolerated to begin with. A rise of temperature, pain, distention and a blocking of the drainage-canals follow in too early and forced feeding. Pus is forced into other abdominal recesses with enlarged patches of peritonitis and adhesions.

The position of the patient should also be considered if there has been a considerable amount of pelvic work done not requiring drainage, and especially if there is a prolapsed stomach elevating the foot of the bed will assist restoration of position and function of the stomach and intestines, often avoiding the possibility of adhesions within the pelvis. Hepatic and splenic kinks of the colon may be overcome at times by this procedure. Many cases should be observed for weeks and months after operation, especially cases of visceroptosis and membranous pericolitis associated with colitis, as by selecting the diet for the patient and insisting on proper exercise and support for maintaining the tone of the abdominal muscles and a suitable course of treatment to overcome the colitis, symptoms formerly the outgrowth of this disease will, as a rule, be permanently removed.

1020 Donaldson Building.

# ERYSIPELAS

## CLINICAL OBSERVATIONS ON 800 CASES, INCLUDING 95 TREATED BY BACTERIAL VACCINE AND 20 TREATED BY PHYLACOGEN

SEWARD ERDMAN, M.D.
Adj. Assistant Surgeon to Bellevue Hospital; Assistant Surgeon to Lincoln Hospital; Instructor in Clinical Surgery, Cornell University Medical College
NEW YORK

The observations which follow are drawn from my experience with 800 cases of erysipelas which have been under my care in the erysipelas wards of Bellevue Hospital during seven periods of service from February, 1909, to April, 1913, an aggregate of forty-two weeks.

### DURATION

So many claims have been advanced for the efficacy of various forms of treatment in limiting the duration or extent of this disease, that I have had especially in mind to determine the average febrile period of various forms of erysipelas (drawn from a large series of cases practically untreated), in order that there might be a background on which the effects of treatment might be contrasted. In reckoning the febrile period, I have counted the days from the onset of the disease until the rectal temperature has remained at or below 100.

1. Uncomplicated facial erysipelas cases (500) ran an average duration of 6.77 days.
2. General body and migratory cases (fifty-six) averaged 14.44 days.
3. Leg cases (thirty-three) averaged in days, 10.88.
4. Complicated cases (211), including facial, body and extremity types of cases in which there was concurrent disease, that is, septicemia, extensive cellulitis, mastoiditis, empyema, tuberculosis, rheumatism, pneumonia, acute alcoholism, etc., were so variously influenced by the complication that an average duration loses significance. But in these cases the average duration is about two weeks

From year to year there was some variation in duration. That is, in 1910 and 1911, the average in days for facial cases was 7.3, whereas in 1913 it was but 6.3. In making up these averages there were numerous cases which lasted only two, three or four days, as well as a number which lasted ten, twelve or rarely twenty days.

### FEVER

The temperature in the facial cases usually was high, that is, from 102 to 104, was remarkably remittent and irregular in type in the majority of cases and the termination was by lysis. The temperature curve in quite a number of them resembled that of lobar pneumonia, rising abruptly to 104 or 105, and there remaining for from five to seven days and falling suddenly as the disease defervesced by a typical crisis. Afebrile cases are rare but I have records of eight such cases of typical facial erysipelas, or 1 per cent. of the series.

### OCCURRENCE

*Sex.*—In our cases at Bellevue among adults, males were affected more often than females in the ratio of 2:1, due, undoubtedly, to their greater exposure to inclement weather, their greater liability to face and scalp wounds, their addiction to alcohol and to less cleanly habits.

*Season.*—Numerically, erysipelas is a disease of the colder and spring months, for in contrasting my periods of service in February and March with those of August and September, the former showed two and one-half times as many cases as the latter; especially was this true of the facial type of cases which were thrice as numerous in the colder months. The prevalence of colds in the head with abrasion of the nasal mucous membrane often affords a point of entry for the infection.

*Age.*—Infants (under 2 years of age), sixty-three cases, approximately, 8 per cent. Children from 2 to 16 years, approximately, 1 per cent. Adults from 20 to 55 years, approximately, 88 per cent.

### ETIOLOGY

The point of entrance of the infection in facial type of cases, which number nearly seven-eighths of all, was through the nasal mucosa in the great majority, who gave a history of a preceding coryza. In others there were abrasions or wounds of the face or scalp, from operations on the nose, from operations for mastoid disease, from eczema of the scalp in infants, etc.

The cases in which there was a wide-spread body involvement either were migratory from the face or extremities or, as was common in infants, began with an infection of the umbilicus, an irritation of the buttocks and vulva or originated about operative wounds of the chest or abdomen. Leg ulcers and wounds accounted for the cases which developed on the extremities.

### ONSET AND COURSE

Chills, general malaise, headache and rise of temperature generally ushered in an attack, and preceded the appearance of the local lesion by from twelve to twenty-four hours; although in many cases the pain, burning and redness of the skin were the first symptoms noted by the patient. Vomiting had occurred in only a few of our cases.

The febrile movement and the duration in the average cases has already been mentioned. Typical facial erysipelas which starts at the bridge of the nose and spreads in butterfly pattern rather symmetrically over the cheeks, may remain thus limited, but in many cases it proceeds to involve the ears, the forehead, the scalp and the neck, down to but not beyond the collar-line, except in the small percentage of cases which are of the migratory type. The characteristic appearance of the lesion, the early bleb-formation and the succeeding desquamation, I shall not attempt to describe.

Erysipelas, which starts on the face or trunk and spreads to the extremities, usually travels down both arms or legs with remarkable symmetry from day to day. Naturally, erysipelas which begins low on an extremity travels upward toward the trunk, the only direction in which it may extend, but I do not believe that this is at all influenced by the lymphatic flow, for I believe that one of the most important points about erysipelas is that it spreads as easily in directions counter to the lymphatic current as with it and that this fact is valuable in differentiating it from the redness of a cellulitis or lymphangitis. The advancing border, too, is usually irregular, with tongue-like projections.

### SEQUELAE AND COMPLICATIONS

Superficial abscesses in the eyelids are very frequent and often there are collections of pus deeper in the cellular tissues of the areas over which the erysipelas has traveled. In other cases septicemia develops with the formation of metastatic abscesses.

Pneumonia is a frequent concomitant, especially in the winter season and among those addicted to alcohol. Nephritis, as shown by albumin and casts, was often a feature of cases in which high temperature was present, but the three deaths due to nephritis were in cases in which nephritis already was chronic.

### RELAPSE AND RECURRENCE

Both are notoriously common in this disease and it would seem that, as in pneumonia, the result of the infection was to lower resistance, rather than to confer a lasting immunity. More than 10 per cent. of our cases gave a history of one or more previous attacks and I feel sure that more careful histories would show a much larger number of such patients. Several patients had had as many as six previous attacks.

### CONTAGION

Is erysipelas an easily communicable disease? In my opinion and experience, it would seem to be not more so than streptococcus and staphylococcus wound infections, cellulitis, abscesses, etc. Undoubtedly erysipelas is inoculable from one part of the body to another and from one patient to another, given a point of entry, but with modern aseptic precautions this should occur no more often than does the infection of a clean wound from a suppurating wound in the next bed in a surgical ward.

My reasons for this opinion are as follows: In our 800 cases there were only four which suggested contagion; in one, a male nurse, who had worked for several months in a ward with twenty erysipelas patients contracted facial erysipelas after a cold in the head. The other three developed before entrance to the hospital and were in children; one nursing infant contracted erysipelas from its mother; the remaining two were in children under 4 years of age whose mothers were coincidently affected.

It is significant that no more than three cases of family contagion occurred in a series of 800, drawn largely from crowded tenement conditions of life; especially when one considers that very many of the patients remained in their homes during three to five days of the disease without any isolation, and also that many returned to their homes while desquamation was still in progress. Mothers frequently continue to nurse their infants in our wards while the infants are passing through an attack of erysipelas, and yet no mothers have contracted the disease. No cases of erysipelas developed in our wards among the very numerous cases of cellulitis and lymphangitis which were admitted under erroneous diagnoses. No cases developed among any of the visitors, nurses or doctors with the exception of the case previously mentioned.

### MORTALITY

In the series of 800 cases there were ninety-three deaths, or 11.625 per cent. The distribution according to sex and age was as follows:

Adult males, 480 cases with 49 deaths or 10.21 per cent.
Adult females, 257 cases with 19 deaths or 7.4 per cent.
Infants (under 2 years), 63 cases with 25 deaths or 39.7 per cent.

According to the lesion the mortality varied as follows:

Facial cases, 500 with 27 deaths or 5.38 per cent.
Body cases, 56 with 28 deaths or 50.0 per cent.
Leg cases, 33 with 9 deaths or 27.3 per cent.
Complicated cases, 211 with 29 deaths or 13.7 per cent.

The type of the disease usual among infants is of the migratory or general body form and hence the mortality is highest among them. As to the facial type of cases it is noteworthy that in the 173 cases in adult women there were but three deaths, or 1.73 per cent. Addiction to alcohol, so common among adult males, accounts in part for the great discrepancy, between the sexes, as it predisposes to acute alcoholism and pneumonia as well as intensifies the toxemia of the disease.

The causes of the ninety-three deaths so far as they may be clinically differentiated, seem to fall under the headings which follow, although the alcoholism and toxemia cases were often combined.

| | |
|---|---|
| Toxemia of erysipelas | 36 |
| Septicemia | 19 |
| Pneumonia | 16 |
| Nephritis | 3 |
| Endocarditis | 3 |
| Acute alcoholism | 16 |

### DIAGNOSIS

The diagnosis of typical facial erysipelas is usually easily made from the characteristic skin appearance, the fever, the bleb-formation and the desquamation, but even here cases are frequently sent in as those of erysipelas when there is merely an area of inflammation about an infected scalp or forehead wound. Erysipelas of the legs or arms or body, unless it be in cases which have extended from the head, presents much more difficulty in diagnosis and I believe that it is often impossible to differentiate cases of erysipelas in the leg from cases of cellulitis or lymphangitis.

Certainly in my experience, about half of all the so-called cases in the leg which were admitted to the erysipelas ward were cases of cellulitis pure and simple, and were at once cleared up either by wet dressings or on giving exit to the pent-up pus, and yet these very cases may have been pronounced erysipelas by competent surgeons and had been transferred on account of such a diagnosis from surgical wards in various hospitals of this city. A visit to the erysipelas wards during August and September when, as has been said, cases of the facial type are much less numerous, rather gives the impression that the wards are those in which patients with cellulitis of the legs and suppurating wounds are being treated.

The great difficulty in making a diagnosis when erysipelas starts on the extremities or the trunk lies in the fact that, in these cases, the *advancing border* is usually less well defined and elevated than in the facial type of cases, perhaps from the presence of a larger quantity of subcutaneous areolar tissue, which is able to accommodate the thickened deeper layers of the skin, without causing marked elevation of the margin.

### TREATMENT

*Internal Medication.*—The administration of iron and of quinin has been long recommended for erysipelas and we have used these remedies in many cases without seeing any striking beneficial results. In fact the iron often deranges the already enfeebled digestion. For this reason in most of our cases no internal medication was prescribed aside from sedatives, stimulants and cathartics as might be needed.

*Local.*—The routine treatment for cases of facial erysipelas in our wards consists in the use of continually wet cold compresses. Beside each bed is a bowl of boric-acid solution in which ice is placed and cloths frequently moistened with the solution are continuously kept on the face. This method is simple, cleanly, harmless to the eyes, inexpensive and seems effectually to relieve the pain and burning in the affected area. For cases in which the leg or arm is involved, wet dressings of boric acid or aluminum acetate are used.

The use of local applications in migratory cases in which there is involvement of the body is more difficult and indeed wet dressings would both be uncomfortable and, in the cold months, might predispose to pneumonia; usually no attempt is made to cover these areas, but occasionally ichthyol is applied or the areas are painted with picric-acid solution.

The use of solutions of phenol (carbolic acid), mercuric chlorid, etc., is dangerous and does not limit the spread of the lesion and accomplishes no more than plain water or boric acid. We have painted the area and circumscribed it with pure phenol, with strong tincture of iodin, with ichthyol, with collodion and with picric acid, only to behold the erysipelas spread readily and rapidly beyond these barriers, unless the case were itself a very circumscribed one, as is often encountered on the face or neck. Phenol, 1:40, we have injected into and under the skin at a distance from the advancing margin, but in each case the disease advanced beyond this line at one or more points, and in one case there resulted a very ugly slough of the skin at the site of the injection. Ichthyol, which is the most widely used local application, does not give the patient as much relief as cold compresses and besides it is dirty and not curative.

### VACCINE TREATMENT

Through the kindness of Dr. T. W. Hastings and Dr. Elser of the Cornell University Medical College Laboratory, and of Drs. Youland and Boehm of the Bellevue Hospital Laboratory, who prepared vaccine for us, we were enabled to use vaccines in ninety-five cases out of the eight hundred.

*Mortality.*—Of the ninety-five vaccine cases, sixty-four were, on admission, of an uncomplicated facial type and there were four deaths; thirty-one were of the leg or body type and showed seven deaths; a mortality of 11.5 per cent. in the ninety-five vaccine cases as against 11.625 per cent. in the whole series of eight hundred cases.

*Duration.*—The average febrile period in the sixty-four vaccine cases of the facial type was 7.8 days; the average in days of the thirty-one cases of the body and leg type was 15.4 days. Both these figures are slightly larger than in the whole series of eight hundred cases, as before noted.

*Immunity.*—Four patients had recurrent attacks of erysipelas within from two to ten days after the attack during which they had been given from five to seven increasing doses of vaccine.

*Limitation of Lesion.*—In cases in which there was localized facial erysipelas on admission, in which vaccine treatment was then instituted, at least seven developed the migratory form of the disease which spread down over the body.

*Effect on Symptoms.*—No constant or significant effects were to be noticed either in the temperature curve or in the symptoms of the disease after these injections, and such irregularities as occurred on the charts were to be found on many charts of untreated cases which were in the wards at the same time.

*Complications.*—Cellulitis and abscesses occurred in some of the vaccine cases as in those not so treated.

*Preparations and Dosage of Vaccines Used.*—In 1909 stock erysipelas vaccines prepared by Drs. Hastings and Elser from a virulent case, were used as follows:

Dr. Hastings' vaccine at intervals of two and three days, in doses ranging from a minimum initial dose of 15 millions up to a maximum final dose of 300 millions. One facial case, after receiving on the fourth, fifth, sixth, seventh and eighth days, respectively, 30, 60, 90, 225 and 300 millions, had an immediate relapse and ran a total fever duration of fourteen days. Dr. Elser's vaccine was given daily in constant dosage of only 6 millions.

In 1910 we used a stock vaccine from a virulent case, in daily doses of 10, 20, 40 millions, thereafter continuing at 40 millions.

In 1911 Dr. Boehm prepared a polyvalent vaccine of a number of strains of streptococci from cases of erysipelas which was given in daily increasing doses; thus 10, 20, 30, 50, 80 millions, rarely exceeding 50 millions.

In 1912 Dr. Youland made up a similar polyvalent vaccine from ten different strains of erysipelas streptococci. This was given in daily doses, beginning with 5 10, 20, 30, 50, 80 millions, rarely exceeding 50 millions. Also a few patients were given one single dose of 100 millions of this vaccine.

### PHYLACOGEN TREATMENT

In February and March of 1913, Parke, Davis & Co. volunteered, through their representative, Dr. Waldecker, to supply us with their Erysipelas Phylacogen for trial in a series of cases. Their representative personally superintended the selection of cases, and the administration of the Phylacogen. As the Phylacogen was used only in one season and not over a period of years we must contrast it with the statistics of all cases in the wards at the same time.

*Mortality.*—We had a total of one hundred eighty cases of erysipelas with nineteen deaths, or 10.6 per cent. The twenty Phylacogen cases showed two deaths, or 10 per cent. Of the Phylacogen cases sixteen were of the facial type, the treatment usually being instituted on the second, third or fourth day.

*Duration.*—The average febrile duration was 6.5 days, whereas in the same period there were 115 facial cases not treated, which showed an average duration of 6.3 days. The four Phylacogen cases of the body type had a duration of 15.75 days, against an average of 13.4 days in the remaining 17 cases not so treated.

That neither immunity nor limitation of the disease were afforded in the Phylacogen cases is instanced by the following:

One man, C. B., during his first attack of facial erysipelas received three injections of, respectively, 2, 4 and 6 c.c. of Phylacogen and was readmitted a few days later with a recurrent attack.

A strong laboring man of alcoholic habit received on the third, fourth, sixth, tenth and nineteenth days of the disease, respectively, 3, 7, 10, 10, 10 c.c., but the disease, at first limited to the face, later spread over the whole body and extremities, with pus formation about the elbow, and death resulted on the twenty-second day.

*Effects.*—After administration of the Phylacogen I could see no constant influence on the temperature. In some cases there was an immediate rise, followed next day by a fall; in others the temperature rose and remained higher; in still others there was no change. In a number of cases the area of injection was very painful and complaint of it was made by the patients.

Inquiries made as to the subjective symptoms showed that a few of the patients felt chilly after the injection, but as concerned relief of pain or discomfort I could elicit no difference between those treated by Phylacogen and those not so treated.

*Administration.*—The injections of Phylacogen were made subcutaneously on successive days, beginning with 2 c.c. and increasing 2 c.c. daily up to but not exceeding 10 c.c., which last dose might be repeated. Just what is represented by this dosage I do not know, for I was not informed.

### CONCLUSIONS

1. Facial erysipelas is a self-limited disease with an average febrile course of less than seven days; therefore any remedy employed must have an immediate effect if it is to influence the course of this form of erysipelas, as many cases do not come under observation until the third or fourth day.

2. Vaccine treatment, as administered in the preceding series of ninety-five cases, will naturally be open to much criticism by enthusiasts in vaccine therapy, and it may be said by one or another that the preparation or the dosage, or the intervals were incorrectly planned and administered. In answer, I can do no more than submit the results as seen in the ninety-five vaccine cases in the series of eight hundred cases and refer again to the fact that different preparations, doses and intervals were to some extent tried out. The difficulty of obtaining cultures and preparing autogenous vaccines and the short duration of the average case, render this form of vaccine very difficult to employ.

From our experience with vaccines in erysipelas I must state that the duration of the disease was not at all lessened, the mortality remained at the same level, and there was no immunity guaranteed against recurrence, against spreading of the lesion, nor were complications, such as cellulitis and abscesses, prevented; from the statements furnished by the patients, moreover, I could not gather that there was any amelioration of the subjective symptoms.

3. By inference from the series of twenty cases treated with Phylacogen, the same conclusions must be drawn. The average duration was as usual, the mortality practically the same, relapses and recurrences also occurred and pus-formation and spreading of the disease occurred in the usual proportion of cases.

# TUBERCULOSIS OF THE GENITAL ORGANS IN CHILDREN *

OLIVER LYONS, M.D.
DENVER

We understand by this title the localization of tuberculosis in the prostate, seminal vesicles, epididymis or testicles. The results of a large series of necropsies by a number of observers show that in children tuberculosis is present in a large percentage of cases. During the first four months it is rare, but it increases rapidly as age advances. In almost every case in which it is found post mortem in the first six months of life, it is thought to be the cause of death, while in older children it is frequently found at necropsy when they have died from other causes. Even in children, tuberculous lesions of the genital organs are no longer museum curiosities, and should receive careful consideration in the classification of diseases that are known to affect these structures.

As a result of the advance in pathologic, histologic and bacteriologic investigation we are able to demonstrate that such cases are to be found and have no restriction as to months or years of life. The frequency, however, with which tuberculous disease of the genital organs occurs in children is still a disputed question.

Hutinel and Deschamps assert that it is as common in infants as in males after puberty. Broca found forty-four in 46,000 cases examined in hospital patients. Jullian found seventeen cases in 5,566 patients in private practice. It would, therefore, seem to be most frequent in private practice.

Tuberculous disease of the testes has been observed at all ages. Dreschfild reports a congenital case; Ashy one at 7 weeks, and Jullian one at 1 month. Bacillary localization in a child is rare, due no doubt to the fact that the testes in children are latent organs, having a scant blood-supply and not so predisposed to blood infection.

According to our theory of tuberculosis of the male genital organs, it is much more common after than before puberty, for it is a well-known fact that tuberculosis is more likely to affect parts in which growth and physiologic functions are most active, as for instance the long bones in children. If the internal secretion of the male genital organs is of any importance in the development of the child, there is no evidence of this activity in the histologic examination of the glands until the age of puberty is reached and the organ prepares itself for its active sexual life. Clinically, the more frequent occurrence of genital tuberculosis between the ages of 20 and 40 would seem to substantiate this theory, for at this period the physiologic activity of the generative organs is at its height.

These organs also at this time of life are more predisposed to injury and infections which so frequently precede tuberculosis in these regions. In ninety-three cases involving the testes in children reported by a number of authors, forty-four were under 2 and forty-seven over 12 years of age; that is to say, about half of the cases occur in the first period of childhood.

Generally it is localized in one testicle; however it often affects both. In the first period of childhood it occurs nearly as often on one side as the other, but after the age of 12 it occurs more frequently on the left side. This is thought to be due to disturbed circulation during walking. In my two cases, the disease was on the left side. There was no history of traumatism, but in both cases a family history of tuberculosis, and whether or not we are justified in attributing the more frequent occurrence on the left side to some difference in the return of the venous blood-supply, the same as the frequency of varicocele on the left side, remains to be proved.

---

* Read in the Section on Genito-Urinary Diseases of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

Tuberculosis of the undescended testicle in infants is very rare. Reference is frequently made, however, to ectopic testes as being predisposed to tuberculosis, yet I know of no undoubted case reported. This may be due to the fact that most all undescended testes are atrophied and the physiologic activity, while present, is very slight.

Just what condition predisposes the male genital organs to tuberculosis is at present imperfectly understood. The observations of different clinicians present no uniform views, and many times they are diametrically opposite. The fact that the disease has become generalized when studied in the post-mortem room is no valid argument for such cases as come to the surgeon presenting local areas of tuberculosis in the generative organs. It is only fair to presume that it may be disseminated from this local area the same as from other organs of the body if this source of infection is not removed.

Personally, I believe that in some cases the male generative organs are the seat of primary tuberculosis. Such cases are, of course, few compared with secondary tuberculosis complicating tuberculous affections of other organs of the body. If the tubercle bacilli enter the circulation they find in the tortuous blood-vessels of the complicated genital tract a favorable condition for their mural implantation, growth and reproduction. The frequent localization in the epididymis may be due to the fact that the spermatic artery divides when it reaches this organ, and the vessels of the epididymis are smaller and more tortuous than those of the testicle and vas proper, the blood-current therefore being slower, which with inherited taint would favor the deposition, growth and reproduction of tubercle bacilli floating in the general circulation.

It has been established by Orth and others that tubercle bacilli can easily penetrate the mucous membrane without leaving any trace. R. C. Rosenberger has demonstrated bacilli in the blood and believes that they appear in this medium at a very early period. In the intestines they insinuate themselves between the epithelial cells like the chyle and are carried to any part of the body or fall a prey to the polymuclear leukocytes. This absorption from the mucous membrane of the intestine undoubtedly plays an important part in tuberculous infection in the child.

My investigations have led me to believe that primary tuberculosis of the prostate and seminal vesicles in children is rare. It is usually considered to be secondary to lesions in the kidney or epididymis. Although there are apparently a few exceptions, I can best illustrate this by a specific instance:

Case 1.—Boy, aged 20 months, was brought to the office June 6, 1904 for circumcision. The mother stated that she had had considerable trouble keeping the baby dry for the last four or five months. Some time before the baby had been fretful, did not nurse, slept little and weighed 3 pounds less than when 17 months old. The child had never been considered healthy. The mother was tuberculous. Examination of patient showed a thin, poorly nourished child. There was considerable excoriation of the skin over the scrotum and inner side of thigh and a long redundant prepuce that could be easily retracted. The meatus was edematous and almost white. During the examination the child passed urine which seemed to be loaded with phosphates. Some of this deposit was collected from the napkin and examined microscopically and found to contain pus. No enlargement of the lymph-nodes could be found. Liver and spleen were enlarged, kidneys could not be palpated. Temperature 100.

A urinary examination was made, June 7, and found to contain pus, blood and tubercle bacilli. The same day the child was catheterized and a guinea-pig inoculated, which was found to be tuberculous five weeks afterward. On rectal examination a large, hard, lumpy mass was found in the region of the prostate and vesicles on the left side. It was difficult to say whether or not this condition extended over to the right side.

On July 11, when the guinea-pig was posted and a definite diagnosis of urinary tuberculosis was made, the child was put on supportive treatment, but the symptoms gradually became exaggerated and the patient died September 25, 1904.

Owing to the objections of the mother I was able to make only a partial necropsy. The chest cavity was found normal. The abdominal cavity and mesenteric lymph-nodes were enlarged, soft and caseous; the liver and spleen enlarged and contained many small nodules on the surface; kidneys normal.

On opening the pelvic cavity and dissecting up the bladder I found a large mass on the left side in the region of the vesicles, which on careful dissection was found to contain the vesicle and ampulla. On section it was found to be filled with caseous nodules and abscess cavities. Bladder negative.

Microscopic examination of this mass, section of liver and spleen, was made by the late Dr. Wilder, and the diagnosis returned to me was tuberculosis. The kidney was found normal.

Judging from this case one would feel that the anatomic evolution of seminal tuberculosis in a child is about the same as that noted in the adult. The only difference is that the Koch bacilli seem to develop more rapidly in an undeveloped organ which, having a feeble blood-supply, cannot resist the infection. Also combative phagocytic power of the cells is less pronounced than after growth has been attained.

As a child cannot interpret its symptoms, rectal examination is necessary for a satisfactory knowledge of the existing condition in the vesicle. The base of the bladder and prostate are easily outlined and any change in form and consistency is readily made out. The source of tuberculous infection is of course the tubercle bacilli, from the tuberculous man or animal.

There are five theories as to the portals of entry into the body: (1) that tuberculosis is always intra-uterine in origin, due to placental infection; (2) that infection takes place from the inhalation of dried tuberculous sputum or fine, moist droplets expelled by coughing; (3) that the source of infection is through the gastro-intestinal tract; (4) that the source of infection is through the urethra, and (5) that infection occurs by metastasis.

As to the first or congenital theory, in the investigation of any case of tuberculosis in a child, the family history is important regarding tuberculosis as well as the history of definite exposure to infection. It is the custom in some places to ridicule the idea of heredity predisposing the offspring to tuberculosis, even if this transmission of the disease from parent to child is not admitted. Certainly it may be said that the child of tuberculous parents will have a predisposition to the disease.

It is quite true that these children may be infected from some other person who has consumption, or through the medium of milk, but this will not explain the cases found in the first few days of life. If there has been tuberculosis in the parents, then the child in adverse circumstances will almost certainly be more liable to contract the disease on exposure to infection than a child whose family history is not marred by the presence of tuberculosis. In other words, if two children of the same age were taken, one with a family history of tuberculosis, the other with no such history, and if these children living under the same environments became exposed, most certainly the child with a tuberculous taint would be the first to contract the disease.

The frequent localization of the tuberculous lesions among children in parts of the body not readily exposed to external infection must be regarded as congenital. Proof of metastatic infection through the blood may be made by microscopic examination, which would show an obliterated blood-vessel in the center of the tuberculous focus. Such pathologic examinations of the lesion may explain the cause of some localized foci of tuberculosis, but we would have a comfortable number of lesions left in which we could not explain the origin.

It is probable that the most common portals of entry are the nasopharynx, tonsils, lungs and intestines, for corresponding to these portals of entry we find primary infection of the cervical, bronchial, and mesenteric lymph-nodes. In many instances these lymph-nodes are primarily effected, the genital lesion being secondary. The difficulty is as to how the infection is to be diagnosed, as in many cases in which the bronchial and mesenteric lymph-nodes are involved the diagnosis would be purely hypothetical. It is a well-known fact that tuberculosis of childhood is essentially a disease of the lymph-vessels, usually represented by a chronic adenitis, and were it not for the fact that Nature has provided the infant with a lymph system of wonderful defensive power, they would all contract tuberculosis, for the infant is more exposed to house infection than any other member of the family—from kisses of a tuberculous person, dirty handkerchiefs and contaminated objects which they carry to their mouths, such as dirt under the finger-nails, which frequently contain tubercle bacilli. All these factors favor the introduction of germs into the digestive tract. The frequency with which the mesenteric lymph-nodes are found involved in infants rather favors the intestine as a more frequent portal of entry.

The entrance of the tubercle bacilli through the urethra must be very rare. It is asserted by some writers that the tubercle bacilli, being devoid of motion, must rely on the circulating currents for its transportation; besides, they are unable to develop in the secretions and are therefore powerless to resist the secretory currents. Nevertheless, urologists are all familiar with the clinical fact that foreign bodies when introduced into the urethra have a tendency to be carried by the mucous currents in the direction of the bladder, and it is reasonable to assume that micro-organisms lodged in the meatus are conveyed in a similar manner along the urethral tract, but unless they become arrested on a soil favorable for their growth they produce no symptoms. But should primary tuberculosis of the urethral tract take place, it would do so only at a point where the mucous membrane has been prepared for their reception by some antecedent injury or disease.

The fact is, the history of tuberculosis in childhood is against any one exclusive portal of entry; but if one clinical fact is as good as another, it is evident that there are several points through which the invasion may take place, and also that when once implanted in the genital tract, advance may be made in more than one direction.

The onset of the disease may be sudden or gradual, and varies with the presence or absence of mixed infection. The truth may be that primary tuberculosis confined to the genital organs of children causes no symptoms, and these children are seldom seen by the doctor for this condition.

The second case I wish to report falls into this class:

CASE 2.—Boy, aged 7 months, seen Sept. 3, 1908. About three or four weeks before, the mother first noticed swelling in the left side of the scrotum. This had gradually increased in size but had caused no pain or other symptoms referable to it. The mother had come to Colorado for tuberculosis three years before. There were no other points of interest.

*Examination.*—General nourishment good. Scrotum presented on left side an ovoid mass about the size of a walnut; several nodules could be felt along the outer side of the mass. On the inner side, high up, a soft mass appeared, surrounded by a hard, fibrous ring. This was thought to be the testicle proper. The spermatic cord was apparently not involved. Rectal examination showed the prostate and seminal vesicles to be normal, as was the opposite testicle. Diagnosis of tuberculosis of the epididymis was made and operation advised, but was refused by parents. The child was seen at odd times until Nov. 25, 1908, when there appeared a softened area in the lower part of the mass. No other changes could be noted. After some time I gained permission of the parents to open this soft area. A considerable amount of thick, caseous material was found. This was diluted with distilled sterile water and guinea-pigs inoculated, which proved positive to tuberculosis when killed in five weeks. Guinea-pigs inoculated with urine at same time were negative. The cavity was packed with iodoform gauze a few times and then let alone, owing to the difficulty of keeping dressings in place. The mass gradually diminished in size, however, the fistula remained open for some months. When the patient was last seen, March 28, 1913, he was in perfect health, the only evidence of his testicular trouble being a rather thick fibrous cord running from the site of incision in the skin to the globus minor.

Tuberculosis of the genital organs is more frequently found in the post-mortem room in children who have died of other diseases. The gradual onset is much more common, as the disease develops painlessly and insidiously. Attention of the mother is usually first attracted by the presence of a swelling of the testicle. This may be first noticed when a complicating hydrocele develops, as this rather sudden accumulation of fluid would more likely attract the mother's attention. Hydrocele is rarely large when due to tuberculosis in the epididymis, and there is very little difficulty in making a diagnosis. In some cases, however, the child is not brought for treatment until caseation has taken place, and attention is first drawn to a discoloration on the scrotum, the swelling being only slightly tender. The following case will illustrate this point:

CASE 3.—In A. J. S., aged 16 months, seen March 20, 1908. Swelling and hardness of the scrotum were noticed two or three months before. A physician was consulted, who advised hot applications.

A few days ago the mother noticed that the swelling was rapidly increasing in size and I was asked to see the case.

The mother's father and one brother had died of tuberculosis. The mother had been sent to Colorado for suspected tuberculosis. The general health of the child had been good; it never had been sick before and there was no history of injury.

*Examination.*—Left scrotum very large, owing to complicating hydrocele. An apparently somewhat enlarged mass was found below and behind the fluid sac. Rectal examination was negative, also the right testicle and epididymis. [illegible] 22 the hydrocele was tapped and 40 c.c. of a cl ing. In my two cases, the disease was on the left side. There was no history of traumatism, but in both cases a family history of tuberculosis, and whether or not we are justified in attributing the more frequent occurrence on the left side to some difference in the return of the venous blood-supply, the same as the frequency of varicocele on the left side, remains to be proved.

Tuberculosis of the undescended testicle in infants is very rare. Reference is frequently made, however, to ectopic testes as being predisposed to tuberculosis, yet I know of no undoubted case reported. This may be due to the fact that most all undescended testes are atrophied and the physiologic activity, while present, is very slight.

Just what condition predisposes the male genital organs to tuberculosis is at present imperfectly understood. The observations of different clinicians present no uniform views, and many times they are diametrically opposite. The fact that the disease has become generalized when studied in the post-mortem room is no valid argument for such cases as come to the surgeon presenting local areas of tuberculosis in the generative organs. It is only fair to presume that it may be disseminated from this local area the same as from other organs of the body if this source of infection is not removed.

Personally, I believe that in some cases the male generative organs are the seat of primary tuberculosis. Such cases are, of course, few compared with secondary tuberculosis complicating tuberculous affections of other organs of the body. If the tubercle bacilli enter the circulation they find in the tortuous blood-vessels of the complicated genital tract a favorable condition for their mural implantation, growth and reproduction. The frequent localization in the epididymis may be due to the fact that the spermatic artery divides when it reaches this organ, and the vessels of the epididymis are smaller and more tortuous than those of the testicle and vas proper, the blood-current therefore being slower, which with inherited taint would favor the deposition, growth and reproduction of tubercle bacilli floating in the general circulation.

It has been established by Orth and others that tubercle bacilli can easily penetrate the mucous membrane without leaving any trace. R. C. Rosenberger has demonstrated bacilli in the blood and believes that they appear in this medium at a very early period. In the intestines they insinuate themselves between the epithelial cells like the chyle and are carried to any part of the body or fall a prey to the polymuclear leukocytes. This absorption from the mucous membrane of the intestine undoubtedly plays an important part in tuberculous infection in the child.

My investigations have led me to believe that primary tuberculosis of the prostate and seminal vesicles in children is rare. It is usually considered to be secondary to lesions in the kidney or epididymis. Although there are apparently a few exceptions, I can best illustrate this by a specific instance:

Case 1.—Boy, aged 20 months, was brought to the office June 6, 1904, for circumcision. The mother stated that she had had considerable trouble keeping the baby dry for the last four or five months. Some time before the baby had been fretful, did not nurse, slept little and weighed 3 pounds less than when 17 months old. The child had never been considered healthy. The mother was tuberculous. Examination of patient showed a thin, poorly nourished child. There was considerable excoriation of the skin over the scrotum and inner side of thigh and a long redundant prepuce that could be easily retracted. The meatus was edematous and almost white. During the examination the child passed urine which seemed to be loaded with phosphates. Some of this deposit was collected from the napkin and examined microscopically and found to contain pus. No enlargement of the lymph-nodes could be found. Liver and spleen were enlarged, kidneys could not be palpated. Temperature 100.

A urinary examination was made, June 7, and found to contain pus, blood and tubercle bacilli. The same day the child was catheterized and a guinea-pig inoculated, which was found to be tuberculous five weeks afterward. On rectal examination a large, hard, lumpy mass was found in the region of the prostate and vesicles on the left side. It was difficult to say whether or not this condition extended over to the right side.

On July 11, when the guinea-pig was posted and a definite diagnosis of urinary tuberculosis was made, the child was put on supportive treatment, but the symptoms gradually became exaggerated and the patient died September 25, 1904.

Owing to the objections of the mother I was able to make only a partial necropsy. The chest cavity was found normal. The abdominal cavity and mesenteric lymph-nodes were enlarged, soft and caseous; the liver and spleen enlarged and contained many small nodules on the surface; kidneys normal.

On opening the pelvic cavity and dissecting up the bladder I found a large mass on the left side in the region of the vesicles, which on careful dissection was found to contain the vesicle and ampulla. On section it was found to be filled with caseous nodules and abscess cavities. Bladder negative.

Microscopic examination of this mass, section of liver and spleen, was made by the late Dr. Wilder, and the diagnosis returned to me was tuberculosis. The kidney was found normal.

Judging from this case one would feel that the anatomic evolution of seminal tuberculosis in a child is about the same as that noted in the adult. The only difference is that the Koch bacilli seem to develop more rapidly in an undeveloped organ which, having a feeble blood-supply, cannot resist the infection. Also combative phagocytic power of the cells is less pronounced than after growth has been attained.

As a child cannot interpret its symptoms, rectal examination is necessary for a satisfactory knowledge of the existing condition in the vesicle. The base of the bladder and prostate are easily outlined and any change in form and consistency is readily made out. The source of tuberculous infection is of course the tubercle bacilli, from the tuberculous man or animal.

There are five theories as to the portals of entry into the body: (1) that tuberculosis is always intra-uterine in origin, due to placental infection; (2) that infection takes place from the inhalation of dried tuberculous sputum or fine, moist droplets expelled by coughing; (3) that the source of infection is through the gastro-intestinal tract; (4) that the source of infection is through the urethra, and (5) that infection occurs by metastasis.

As to the first or congenital theory, in the investigation of any case of tuberculosis in a child, the family history is important regarding tuberculosis as well as the history of definite exposure to infection. It is the custom in some places to ridicule the idea of heredity predisposing the offspring to tuberculosis, even if this transmission of the disease from parent to child is not admitted. Certainly it may be said that the child of tuberculous parents will have a predisposition to the disease.

It is quite true that these children may be infected from some other person who has consumption, or through the medium of milk, but this will not explain the cases found in the first few days of life. If there has been tuberculosis in the parents, then the child in removed, as well as the iliac lymph-nodes. The patient is still alive and has had no recurrence.

Case 2.—M. D., aged 24, single, farmer, was admitted to Douglas County Hospital Jan. 1, 1913. Family history is negative; personal history is also negative except for the following: The patient was thrown on the horn of a saddle six years ago and injured the right testicle. The organ enlarged, later became hard and caused a dragging pain. He says a hernia appeared last June, which caused him a great deal of trouble. Three years ago he fell over a piece of timber and hurt himself in the region of the stomach, but noticed no discomfort from it later.

Three months ago he sprained his back in lifting a sack of wheat into a wagon-box, and three days later he rode a horse and noticed that his abdomen was painful. At first they were cramp-like pains. The pain increased and the abdomen became hard and tender. It has gradually increased in size from the time of the sprain. Appetite has been poor for the last month and eating caused cramps. Bowels have been irregular and difficult to move.

Genito-Urinary: Did not have to get up at night before injury, nor was there pain or burning; but since being hurt he has had pain, burning and difficulty in urination. Sometimes has to be catheterized.

Hospital records from January 1 to January 5 show that the patient had a tense abdomen, complained of pain after eating, was restless, had severe pain in abdomen and back not related to eating, and rested only under the influence of morphin. During this time his temperature ranged between 96.6 and 100.6 F., respiration 20 to 26 and pulse from 86 to 130.

*Operation.*—On January 5 he was operated on, the right testicle being removed and the abdominal mass drained. Subsequent to the operation there was great increase in the rate of the heart; later the pulse, temperature and respiration were between the limits given above. There was considerable postoperative hemorrhage and discharge of sanguineous material and cell detritus through the drain, but the patient rested fairly well and on January 12 complained of no pain. On the night of January 13 he complained of severe pain in the left ear, and on January 15 there was a discharge of a large amount of watery fluid. At 4 p. m. there was about 20 ounces of dark-green emesis. At 8 p. m. the pulse became weak; later the pulse and respiration began to fail, and patient died at 11 p. m.

*Necropsy.*—The findings have no bearing on the tumor, except the following:

Liver much enlarged, adherent to diaphragm in entire extent of contact. Greater part of liver substance is replaced by a reddish-gray, purulent fluid resembling anchovy sauce. Weight about 1,500 gm. (does not include fluid; Orth gives the weight of the liver for adults as varying from 1,000 to 2,000 gm). Adhesions between transverse colon and stomach. Colon bound down in entire extent by adhesions.

Tumor, in upper abdomen, and apparently retroperitoneal. There is a large mass to which the small and large intestines are adherent. This mass contains a large amount of semifluid, chocolate-brown substance like anchovy sauce, in which are curd-like masses. The fluid is very abundant and spurts forth actively as the incision is made into the degenerated tumor mass.

Right testicle previously removed. Left apparently normal. Weight plus epididymis and appendages, 37 gm.

Lungs large, no adhesions; some anthracosis; some discolorized areas; anemia; some edema. Some areas cut with normal elasticity, but greater part of lung tissue is replaced by areas of same material as in the tumor and liver. In the upper right lobe an area of tuberculous appearance is found; cut across it is gritty to the knife.

Heart normal. Shape normal. Color slightly anemic. Consistency rather firm.

Lymph-nodes of neck filled with same pus-like material as found elsewhere.

*Microscopic.*—Liver: Accumulation of pigment, evidently both of hematogenous and hepatogenous origin, about the central vein and Glisson's capsule, especially the former. Some small round-cell infiltrations, especially about capsule. Marked congestion; increased connective tissue in capsule; general fatty degeneration. Area of metastasis: Areas of large round cells; much connective tissue, also congestion and some small round-cell infiltration. Area shows marked cystic degeneration.

Lungs: Emphysema; anthracosis slight; atelectasis, congestion, some blood pigment, some small round-cell infiltration, especially beneath pleura. Area of calcification: Tuberculous nodule surrounded by connective tissue, and small round-cell infiltration marked.

Tumor: Mixed type, no regularity in formation of tissue cells; there are spindle-cells, some small round cells, and a few large round cells, all probably of connective tissue origin. Pus cells are numerous and there is much degeneration and necrosis so that the blood-vessels are not apparent. There are cell nests composed of cells epithelial in character.

Right testicle: Some parenchymatous degeneration; slight increase in connective tissue; marked congestion.

Left testicle: Shows areas of round-cell infiltration; large amounts of free blood; lymph stroma contains alveolar areas of epiblastic tissue and areas resembling the corium, showing syncytial cells with Langhan's cells and areas of cartilage.

These two cases present many points of interest. In the first there was no sign of metastases except those referred directly to the testicle. The cord was not enlarged to any extent and the entire tumor seemed to be local. We made an incision extending from the symphysis pubis to the anterior superior spine and removed the testicle, the cord, the retroperitoneal fat and the cord around the pubis with all its veins and tributary blood-vessels and lymph-nodes that we could find nearly to the prostate.

The patient made an uninterrupted recovery and is still living, two and a half years after the above.

The second case was seen late in its history. With the distended abdomen and the tuberculous family history, the intern in the hospital made a diagnosis of tuberculous peritonitis with the possibility of a tuberculous epididymis. The patient was anesthetized and the abdomen opened only to find the peritoneal cavity empty and the mass entirely retroperitoneal with liver metastases. The mass was a soft, bloody, grumous looking material resembling anchovy sauce. The testicle was removed. In three days the patient died, and at the post-mortem specimens were taken from the lungs, liver, thyroid, glands of the neck and kidneys, with the result enumerated before.

On microscopic study of the slides from these sections the diagnosis of mixed tumor of the testicle was made.

In the first case, after a careful study, we found the dominant cells to be epithelial, while in the second, at least in the metastatic growths, the dominant cell was of mesoblastic origin, with many epiblastic cells as well as mesoblastic in the testicle itself.

A complete review of the literature and theories of these tumors and their origin would carry us too far into the field of pathology for this paper, and we can only call attention to the recent papers of Ewing[1] and of Wilson.[2] Ewing has given us such a masterly review of the subject that little remains to be said regarding these peculiar tumors.

Our cases are, in our judgment, both of embryologic origin, as evidenced by the presence of syncytium and the cells of Langhans, the increased amount of muscle and the presence of cartilage, the large embryonal epiblastic cells arranging themselves in an alveolar form, the prescolored fluid removed. This fluid was not examined. After removing the hydrocele fluid it was possible to make out a hard indurated epididymis. The testicle did not seem to be involved, as it was possible to make out the line of demarcation between the testicle and the epididymis. The vaginalis process was closed and the vas was apparently uninvolved. Diagnosis of tuberculosis was made, but operation refused. March 29 there was no change except a slight reaccumulation of hydrocele fluid. April 30, after a few days' application of heat, which had been advised by the previous medical attendant, the child became fretful and cross. An area of redness appeared over the lower part of the indurated mass. After doubly assuring the father that this area contained pus, I was allowed to open and drain this softened area and a teaspoonful of pus was removed. The cavity was then packed with iodoform gauze. The child was seen the next day and the gauze removed and the cavity repacked. May 3, the previous packing had been removed the day before and it was impossible to reinsert the gauze. Nothing more was done to the fistula other than keep it clean. June 17 another soft area appeared on the upper and outer side of the scrotum. The fistula below was still discharging a small amount of pus. This was opened and drained and treated as the previous abscess had been. The pus was examined for tubercle bacilli but none could be found. The fistula remained open for many weeks but finally closed.

---

[1] Ewing: Surg., Gynec. and Obst., October, 1910.
[2] Wilson: Ann. Surg., April, 1913.

When this patient was last seen, in May, 1912, he was in good health and the testicle appeared normal. A small, firm band was found running from the scar on the scrotum to a rather small hard nodule in the epididymis. The tuberculous process had here been arrested and encapsulated.

Acute tuberculosis of the epididymis and testes is rare, and begins like gonorrheal epididymitis, suddenly and with acute symptoms. There is pain on palpation, the scrotum is edematous, with effusion into the tunica vaginalis, and the testicle enlarges to two or three times its natural size.

In most of these cases it is quite probable that some previously existing tuberculous nodules in the organ were present and not noticed by the mother. Abscess formation is quite rapid, and the pus may find its way to the surface and break externally, or burrow into the testes proper. A portion or all of this organ may be destroyed if the disease was primarily in the epididymis.

I have seen similar cases in the adult in which the patient would come down with a sharp, acute epididymitis on one side after severe exercise, and on examination of the other epididymis, prostate, and vesicles, find tuberculous nodules that had never been noticed by the patient.

In the case in which the prostate and seminal vesicles were found infected, frequent urination was the first symptom noticed by the mother, but as the case progressed the irritability became so marked that the patient was unable to retain his urine more than twenty to thirty minutes at a time. Tenesmus and pain became very severe toward the last in this case, for this little fellow had a crying spell after each urination.

The two patients with infection of the epididymis appeared to be in perfect general health, and nothing could be found suggestive of tuberculosis in any other organs of the body; but the patient with infection of the prostate and vesicles presented a typical tuberculosis appearance. There was loss of weight and strength, the temperature fluctuating between 99 and 101.

In the differential diagnosis, congenital syphilitic orchitis is the most common and the most difficult disease of the testes to exclude. The chief points in the diagnosis are the presence of other signs of congenital syphilis and the therapeutic test. The body of the testes is usually affected in the majority of cases as a diffused enlargement, but gumma may occur in the epididymis. The cord is rarely thickened; the prostate and vesicles never. Syphilis is almost always painless. A Wassermann reaction may be negative, but it may be possible for a syphilitic child to have a tuberculous testicle.

Sarcoma is the next frequent disease likely to attack the testicles in children, but it can usually be recognized by the rapidity with which the testicle increases in size without pain, softening or inflammatory symptoms. The cord is often enlarged, but the swelling is smooth and even. The lymph-nodes above and below Poupart's ligament may be involved early, but clinically, from the standpoint of treatment, they may be considered as one.

Hydrocele usually presents no difficulty of diagnosis. It should be remembered, however, that this condition is often a part of the tuberculosis of the testes and epididymis.

Benign tumors of the testicles, such as enchondroma, myoma, adenoma, etc., are of such rare occurrence that they need not be considered in the differential diagnosis.

The prognosis in primary tuberculosis of the genitals in children is usually favorable. Even when secondary infection has taken place and the abscess cavity opens externally, encapsulation takes place and a portion of the glandular structure is preserved. In fact, there seems to be a limitation of the tuberculous process in all organs of children, the one notable exception being tuberculous meningitis.

For the true conception of these cases, it is of importance to know that tuberculosis of these organs remains almost always the only tuberculous focus in the body; differing from later periods of life when it is frequently secondary to other tuberculous processes in the genito-urinary tract. Therefore operation may produce permanent cure, although this is not always certain.

In spite of the result obtained in these two cases, I should always advise operation.

# THE PROBABLE EMBRYOLOGIC ORIGIN OF MIXED TUMORS OF THE TESTICLE *

A. C STOKES, M.D.
Professor of Genito-Urinary and Experimental Surgery, University of Nebraska, College of Medicine
OMAHA

In presenting this paper I do not hope to add any new facts to those already accessible, only to bear witness to the position taken in the literature regarding the pathology and probable origin of mixed testicular tumors. In the last two years I have met with two cases of tumor of the testicle worthy of attention.

CASE 1.—O. M., waiter, colored, aged 29, was seen early in 1911. He gave a negative family and personal history, especially in regard to new growths. As seems to be the usual thing in these cases, he gave a history of an injury to the testicle at the age of 12 years, but had no trouble to speak of till about ten months before we saw him. He did say that he had had dull pain in this testicle at times for ten years previously, and that the testicle seemed larger than the other. During the three months before coming to us it became much larger and more painful. The testicle was

---

* Read in the Section on Genito-Urinary Diseases of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

removed. as well as the iliac lymph-nodes. The patient is still alive and has had no recurrence.

Case 2.—M. D., aged 24, single, farmer, was admitted to Douglas County Hospital Jan. 1, 1913. Family history is negative; personal history is also negative except for the following: The patient was thrown on the horn of a saddle six years ago and injured the right testicle. The organ enlarged, later became hard and caused a dragging pain. He says a hernia appeared last June, which caused him a great deal of trouble. Three years ago he fell over a piece of timber and hurt himself in the region of the stomach, but noticed no discomfort from it later.

Three months ago he sprained his back in lifting a sack of wheat into a wagon-box. and three days later he rode a horse and noticed that his abdomen was painful. At first they were cramp-like pains. The pain increased and the abdomen became hard and tender. It has gradually increased in size from the time of the sprain. Appetite has been poor for the last month and eating caused cramps. Bowels have been irregular and difficult to move.

Genito-Urinary: Did not have to get up at night before injury, nor was there pain or burning; but since being hurt he has had pain, burning and difficulty in urination. Sometimes has to be catheterized.

Hospital records from January 1 to January 5 show that the patient had a tense abdomen, complained of pain after eating, was restless, had severe pain in abdomen and back not related to eating, and rested only under the influence of morphin. During this time his temperature ranged between 96.6 and 100.6 F., respiration 20 to 26 and pulse from 86 to 120.

*Operation.*—On January 5 he was operated on, the right testicle being removed and the abdominal mass drained. Subsequent to the operation there was great increase in the rate of the heart; later the pulse, temperature and respiration were between the limits given above. There was considerable postoperative hemorrhage and discharge of sanguineous material and cell detritus through the drain, but the patient rested fairly well and on January 12 complained of no pain. On the night of January 13 he complained of severe pain in the left ear, and on January 15 there was a discharge of a large amount of watery fluid. At 4 p. m. there was about 20 ounces of dark-green emesis. At 8 p. m. the pulse became weak; later the pulse and respiration began to fail, and patient died at 11 p. m.

*Necropsy.*—The findings have no bearing on the tumor, except the following:

Liver much enlarged, adherent to diaphragm in entire extent of contact. Greater part of liver substance is replaced by a reddish-gray, purulent fluid resembling anchovy sauce. Weight about 1,500 gm. (does not include fluid; Orth gives the weight of the liver for adults as varying from 1,000 to 2,000 gm). Adhesions between transverse colon and stomach. Colon bound down in entire extent by adhesions.

Tumor, in upper abdomen, and apparently retroperitoneal. There is a large mass to which the small and large intestines are adherent. This mass contains a large amount of semifluid, chocolate-brown substance like anchovy sauce, in which are curd-like masses. The fluid is very abundant and spurts forth actively as the incision is made into the degenerated tumor mass.

Right testicle previously removed. Left apparently normal. Weight plus epididymis and appendages, 37 gm.

Lungs large, no adhesions; some anthracosis; some discolorized areas; anemia; some edema. Some areas cut with normal elasticity, but greater part of lung tissue is replaced by areas of same material as in the tumor and liver. In the upper right lobe an area of tuberculous appearance is found; cut across it is gritty to the knife.

Heart normal. Shape normal. Color slightly anemic. Consistency rather firm.

Lymph-nodes of neck filled with same pus-like material as found elsewhere.

*Microscopic.*—Liver: Accumulation of pigment, evidently both of hematogenous and hepatogenous origin, about the central vein and Glisson's capsule, especially the former. Some small round-cell infiltrations, especially about capsule. Marked congestion; increased connective tissue in capsule; general fatty degeneration. Area of metastasis: Areas of large round cells; much connective tissue, also congestion and some small round-cell infiltration. Area shows marked cystic degeneration.

Lungs: Emphysema; anthracosis slight; atelectasis, congestion, some blood pigment, some small round-cell infiltration, especially beneath pleura. Area of calcification: Tuberculous nodule surrounded by connective tissue, and small round-cell infiltration marked.

Tumor: Mixed type, no regularity in formation of tissue cells; there are spindle-cells, some small round cells, and a few large round cells, all probably of connective tissue origin. Pus cells are numerous and there is much degeneration and necrosis so that the blood-vessels are not apparent. There are cell nests composed of cells epithelial in character.

Right testicle: Some parenchymatous degeneration; slight increase in connective tissue; marked congestion.

Left testicle: Shows areas of round-cell infiltration; large amounts of free blood; lymph stroma contains alveolar areas of epiblastic tissue and areas resembling the corium, showing syncytial cells with Langhan's cells and areas of cartilage.

These two cases present many points of interest. In the first there was no sign of metastases except those referred directly to the testicle. The cord was not enlarged to any extent and the entire tumor seemed to be local. We made an incision extending from the symphysis pubis to the anterior superior spine and removed the testicle, the cord, the retroperitoneal fat and the cord around the pubis with all its veins and tributary blood-vessels and lymph-nodes that we could find nearly to the prostate.

The patient made an uninterrupted recovery and is still living, two and a half years after the above.

The second case was seen late in its history. With the distended abdomen and the tuberculous family history, the intern in the hospital made a diagnosis of tuberculous peritonitis with the possibility of a tuberculous epididymis. The patient was anesthetized and the abdomen opened only to find the peritoneal cavity empty and the mass entirely retroperitoneal with liver metastases. The mass was a soft, bloody, grumous looking material resembling anchovy sauce. The testicle was removed. In three days the patient died, and at the post-mortem specimens were taken from the lungs, liver, thyroid, glands of the neck and kidneys, with the result enumerated before.

On microscopic study of the slides from these sections the diagnosis of mixed tumor of the testicle was made.

In the first case, after a careful study, we found the dominant cells to be epithelial, while in the second, at least in the metastatic growths, the dominant cell was of mesoblastic origin, with many epiblastic cells as well as mesoblastic in the testicle itself.

A complete review of the literature and theories of these tumors and their origin would carry us too far into the field of pathology for this paper, and we can only call attention to the recent papers of Ewing[1] and of Wilson.[2] Ewing has given us such a masterly review of the subject that little remains to be said regarding these peculiar tumors.

Our cases are, in our judgment, both of embryologic origin, as evidenced by the presence of syncytium and the cells of Langhans, the increased amount of muscle and the presence of cartilage, the large embryonal epiblastic cells arranging themselves in an alveolar form, the presence of large round cells, degenerating epiblast and chromogenetic cells.

---

[1] Ewing: Surg., Gynec. and Obst., October, 1910.
[2] Wilson: Ann. Surg., April, 1913.

As to the probable origin of these tumors, the first case seemed definitely to arise from the tubules of the testicle, or, at least, the tubules presented the microscopic appearance of infiltrating the lower layers of the tissue in their proximity. This tumor would, therefore, be readily classified as a carcinoma on superficial examination.

A microscopic study of the second tumor offered no evidence regarding its origin. The last would undoubtedly fall under the theory of Ewing, that these tumors arise in the sex cells of the testicle; the first did not appear to me to be nearly so indefinite in its origin.

Once again the conclusions of Ewing and the added ideas of Wilson may be quoted, as follows:

1. Pure fibromas and pure leiomyomas of the testis exist but are extremely rare, as is also adenoma occurring in atrophic undescended testes.
2. Primary lymphosarcoma and pure spindle-celled sarcoma are of uncertain origin.
3. Chondroma, myxoma, lipoma, rhabdomyoma and carcinoma have not been shown to exist apart from a teratomatous origin.
4. Alveolar large round-celled, perivascular and other forms of so-called sarcoma testis are of epithelial and teratomatous origin.
5. The commonest tumor of the testis is an embryonal carcinoma, alveolar or diffuse, with polyhedral or round cells and often with lymphoid stroma. These tumors are probably one-sided developments of teratomas.
6. Teratoma testes arise from sex cells in the neighborhood of the rete, whose normal development into spermatogonia has been suppressed but whose potencies remain intact and ready to express themselves in the various forms of simple or complex teratomas.

Wilson's application of the theories of Blanca and Bresseto would also further tend to prove the hypothesis of Ewing, that these tumors are of sex cell origin, and are teratomas.

We believe we are justified in concluding that these two cases fall under the classification of teratomas. We note that Wilson reports six of the nineteen cases as having had previous injury. Both of our cases reported injury.

From a clinical standpoint the question comes: What is to be done with tumors of the testicle? From the evidence gathered from recent studies it would seem that tumors of the testicle, like those of the breast and parotid, are at least frequently malignant.

Given a history of trauma some years previously, with a testicle slowly increasing in size, accompanied by rather indefinite pains, continued for several months, one is justified in removing the testicle for malignancy. Some may take issue with this position, but we believe that were this done many lives would be spared, and perhaps a few benign tumors removed. Our two cases illustrate also the two extremes of duration; in one case the tumor was attacked early, and in the other late. Just at what period in the histories of these cases metastasis takes place is not clear. In general it is early, we believe. The simple removal of the testicle is, in our judgment, not indicated, even if a malignant tumor is suspected; rather the removal of the entire cord, the retroperitoneal glands along the cord and as far as possible along the iliac veins, for evidently metastasis takes place frequently along this channel as indicated by the formation of retroperitoneal masses, as the late results of these tumors frequently show. Clinically it is important to recognize them as early as possible and to do a radical operation on them.

# OPERATIVE TREATMENT OF GENITAL TUBERCULOSIS

## INDICATIONS AND TECHNIC *

HUGH CABOT, M.D.
Chief of Genito-Urinary Department, Massachusetts General Hospital
AND
J. DELLINGER BARNEY, M.D.
Genito-Urinary Surgeon to Outpatients, Massachusetts General Hospital
BOSTON

Most of us probably hark back to the old terminology under which we were brought up which regarded genito-urinary tuberculosis as a variety of starfish beginning in the bladder and radiating more or less completely in all directions. Certain remnants of this teaching still exist, and though tuberculosis of the kidney is now generally recognized as a primary lesion for the urinary tract, it is too little recognized that the genital tract also has its primary focus of infection. The term "genito-urinary tuberculosis" should be abandoned and we should come to recognize tuberculosis of the urinary tract as primary in the kidney, while tuberculosis of the genital tract in the male is primary in the epididymis. The bladder and the structures of the bladder neck, including the prostate, are more or less common to both genital and urinary tracts, and the prostate is therefore between two fires and may be infected with tuberculosis as a secondary matter either in urinary or in genital tuberculosis. It is important, however, to recognize that the infection of the prostate is rarely primary for the genital tract, and as our knowledge of this matter extends we incline to think that primary prostatic tuberculosis will be relegated to the same class of surgical curiosities as is primary tuberculosis of the bladder.

Our knowledge of infections of the genital tract have been crystallized by the excellent work of Belfield. Perhaps his most important contribution has been in calling attention to the excretory function still maintained by the genital duct. It will be recalled that the epididymis is the remnant of the old middle kidney, and in its rudimentary excretory capacity it picks up microorganisms from the circulation in a manner entirely similar to that of the kidney. Since the prostate has no such function it is easy to comprehend why it is so rarely infected as a primary matter, though its position makes it easy to recognize the probability of its secondary involvement. One of us (J. D. B.) has shown in a recent paper[1] that the presence of primary prostatic tuberculosis is asserted in only 6 per cent. of a large collection of well-studied cases.

The relation of the testicle to genital tuberculosis is also of paramount importance. Its proximity to the epididymis makes its secondary involvement an exceedingly easy matter, and this complicates our opinion as to the relation between the epididymis and the testicle in regard to primary involvement. It is our firm opinion, based on a considerable clinical observation, that primary involvement of the testicle is rare; but we are free to admit that it was involved to some extent in the process in over 40 per cent. of our cases of tuberculosis of the epididymis. Our opinion is therefore based on

---

* Read in the Section on Genito-Urinary Diseases of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

[1] Barney, J. Dellinger: Med. and Surg. Jour., Boston, July 3, 1913.

the character of the process in the testicle, which appeared to be more recent and less extensive than that in the epididymis. This question is of importance as bearing on the attitude we should take in regard to removal of the testicle in tuberculosis of the genital tract, and also in regard to the importance of early operation on the tuberculous epididymis if we are to save the testicle from infection. It is only a comparatively short time since the operation of orchidectomy was regarded by the highest authorities as the operation of election for these conditions. Sound opinion has, we believe, entirely reversed this decision, but its stamp still remains on the surgical world and it is no rarity to see orchidectomy done when the involvement of the testicle by no means warrants it.

That the process reaches the prostate in a large number of the cases of genital tuberculosis has recently been shown by one of us (J. D. B.)[1] in an analysis of 101 cases from our clinic, where it was clinically present in 75 per cent. A more searching examination of these cases shows that 30 per cent. are involved in the first six months of the disease and 54 per cent. in the first year. The route by which the infection reaches the prostate is not yet clearly understood. Examination of the vas shows progressive involvement from below upward, but in few, if any, of the cases is the involvement sufficient to justify the belief that the involvement of the prostate takes place by continuity of the process. It seems fairly clear that the infection must extend by blood-stream or lymph-vessels, and we incline to the view that the lymphatic route is more common than has been generally believed.

Briefly restated, the clinical pathology of genital tuberculosis is as follows: The disease is primary in the epididymis, occasionally in the testicle, rarely in the prostate. The prostate is involved secondarily early in the disease and ultimately in a vast majority of the cases. The testicle is involved secondarily less often than the prostate and probably less early. It is of the first importance to recognize the distinction between primary and secondary involvement. The organs primarily involved show very little tendency to shake off the disease, while those in which it is secondary show a far greater power in this direction and will under favorable conditions be successful. On these facts we shall undertake to support our main thesis that the operation of election in genital tuberculosis is epididymectomy, including the accessible portion of the vas.

It has become a generally accepted doctrine when dealing with tuberculous processes elsewhere in the body that it is wise to remove by operation massive foci and to trust to the tissues the jugulation of the remaining tuberculosis. This principle applied to the urinary tract requires nephrectomy with removal of the accessible portion of the ureter, and it is generally recognized that the secondary processes in the remaining portion of the ureter and in the bladder heal in a majority of cases. Precisely the same principles should be applied to genital tuberculosis. The primary focus, the epididymis, should be dealt with radically. The secondary foci in the testicle may be dealt with locally and the secondary process in the prostate should be left to Nature. The last statement requires some explanation. If we advise dealing locally with the process in the testicle why not give the same advice in regard to the prostate? The difference depends on its anatomic location. To attack the tuberculous prostate is a radical procedure. The complete removal of the process when not under guidance of the eye is practically out of the question. We are far more likely to simply kick a hornet's nest and leave the patient worse off than when he started. In spite of some evidence to the contrary, we have been unwilling to attempt operative measures on the tuberculous prostate.

The management of the process in the testicle requires some further discussion. It has been our experience that the involvement of the testicle was in most cases contiguous to the process in the epididymis. Often only a small focus in one pole is to be found. When this is the case we have been satisfied to eradicate roughly with the curet and have never seen reason to regret it. It is clear that the testicle offers a very much higher resistance to the process than that offered by the epididymis. Cases will occasionally be seen, however, in which the involvement of the testicle is so considerable that it cannot be regarded as a harmless process; in these, though few, we must recommend orchidectomy.

We have held views somewhat at variance with generally accepted doctrines in regard to our duty toward the vas, and therefore feel required to give our reasons for the faith that is in us. We have insisted that it was desirable to remove the accessible portion of the vas for the reason that in years gone by we have too frequently seen recurrence in the stump of the vas when it was left in the neighborhood of the inguinal canal. Too often we have patients returned with scrotum perfectly healed and testicle apparently free from involvement, but with a troublesome mass in the groin or even a sinus, the healing of which required time, patience and tuberculin. We have therefore come to the opinion that the leaving of this portion of the vas complicates convalescence and may at times prove a serious annoyance. For these reasons we have recommended, and for five years one of us (H. C.) has practiced removal of the epididymis and removal of the vas up to a point at about the level of the brim of the true pelvis.

## OPERATIVE TECHNIC

The local preparation of the patient should involve the skin of the scrotum and the groin of the corresponding side if the disease is unilateral. An incision is made over the epididymis about 2 inches long. If sinuses are present they should be circumscribed by the incision. This is carried down to and opens the tunica vaginalis, which will in many cases be found adherent to the testicle and must be separated by dissection. The testicle and epididymis are delivered from the wound. The epididymis is then separated from the testicle by a scissor dissection, as in this way the vessels which lie behind the epididymis are less likely to be destroyed. The separation should be begun at the upper pole and carried downward, the epididymis being separated from within outward. When it is free the lower inch or two of the vas should be stripped up by blunt dissection from the structures of the cord. A curved clamp is then applied to the vas and the epididymis and the lower inch or two of the vas cut away. The vas is then stripped up by blunt dissection with the fingers so as to free it from the structures of the cord up to the external inguinal ring. Guided by the finger, the clamp on the lower end of the vas is then passed up to the external ring and carefully inserted into the canal, care being taken to avoid pushing it in front to the canal between the fascia and the fat. The clamp is then pushed upward and outward, following the line of the inguinal canal until its tip lies directly beneath the fascia at the level of the internal inguinal ring. The handle of the clamp is then strongly depressed, bringing the point snugly against the skin. An incision not over half an inch in length is then made on the point of the clamp, which is then pushed out through this incision carrying with it the distal end of the vas (Fig. 1). The vas is then picked up, and traction is made so as to pull out the portion lying in the canal so that the remaining portion dives vertically into the wound and over the brim of the pelvis. The finger is then inserted into the little wound, as shown in Figure 2, and the vas is freed as far as the finger can reach, making steady traction during this process. A right-angled clamp is then applied to the vas at the lowest accessible point. It is divided, cauterized with phenol (carbolic acid) and dropped back. The wound in the groin is closed with one catgut suture and the fascia with a silkworm-gut stitch in the skin. The operation is completed by the careful ligation of any bleeding points in the scrotum. Any apparent foci in the testicle are eradicated with a curet. The wound is painted with tincture of iodin and closed with a subcuticular suture of silkworm-gut, leaving a small protective tissue-drain at the lower angle. This drain has been found to shorten convalescence by giving free exit to the serum which necessarily oozes from the raw surface, the amount of which is considerably increased by the application of iodin. The dressing is held in place by the application of an Alexander bandage, one of the many devices of the late Samuel Alexander, which has been a boon to the genito-urinary surgeon. The drain can generally be removed in forty-eight hours and the patient may be up and about in two or three days. *The after-treatment should include* all of the general hygienic measures suitable for patients with tuberculosis, including the routine use of tuberculin and the routine use of sandalwood oil in cases in which there is involvement of the prostate.

The operation has seemed to us much superior to that involving a long incision through the scrotum and coverings of the inguinal canal in order to remove an equal amount of the vas. It takes less time in the doing, is equally efficient and shortens the convalescence about two-thirds.

87 Marlboro Street—374 Marlboro Street.

## ABSTRACT OF DISCUSSION

### ON PAPERS OF DRS. STOKES, LYONS AND CABOT AND BARNEY

Dr. Louis E. Schmidt, Chicago: I am not in complete sympathy with the technic of Dr. Cabot. About ten years ago we had a tendency to remove as much of the vas as possible. Of late years there has been, I believe, an opposite tendency, and I have simply removed the epididymis and a short portion of the vas, and treated the vas in exactly the same manner as the Mayos treat the ureter; they inject a certain quantity of phenol (carbolic acid) and tie it off, and then cleanse the wound with saline solution. That has given good results. Naturally, if there is a question of the involvement of the vas, if nodules can be felt all along its course, the question will arise as to how far you should remove the vas, whether or not it should be removed high up close to the internal ring in fact, if it is involved beyond that point, and particularly if the vesicles are involved, it is a question whether or not the removal of the vesicles should be undertaken. Formerly I was in the habit of removing them, and I have specimens to show both testicles removed. when they have been involved by tuberculosis, together with both cords and both seminal vesicles. They can be removed intact, that is, with an incision along the groin and then a perineal incision. So far as I am familiar with this topic at present, if the vesicles are involved, the prostate is also involved, and there is a greater tendency to leave these alone, particularly if the primary focus is in the epididymis; if the epididymis is removed there is a tendency to improvement, as in the kidney, and I think that we should leave the larger part of the ureter in rather than attempt to make a ureterectomy, even if we know that the ureter is involved.

Dr. Hugh Cabot, Boston: We have all seen patients known to have tumors in the scrotum who had been treated in some cases for months, and occasionally longer, under the belief that the change in the testicle might be due to syphilis. In that way I have, on at least two occasions, seen a tumor grow so rapidly that it was at least arguable that the patient's life was thrown away, and I do not believe that in the present state of our knowledge we are justified in observing these cases of unknown tumors involving the testicle. The Wassermann reaction may often exist, but assuming the Wassermann reaction to be negative, assuming that there is still doubt in our minds as to the possibility of the change in the testicle being gummatous, it is our duty to give the patient the benefit of the doubt and operate, and not sit back and make an attempt to cure him with antisyphilitic treatment. We shall probably never succeed in convincing the average practitioner of the truth of that statement. We must recognize the extreme malignancy of these tumors, the fact that, as we have been in the habit of managing them, the vast majority are not benefited by operation, that these patients die of involvement of the lymph-nodes, and that it is abundantly clear that we have not seen these cases early enough to be of substantial value to the patient. The remedy for that consists in enforcing the view that exploration in these cases is the method of giving the patient the benefit of the doubt and that the doubt should be removed by seeing exactly what is going on there.

I am not quite in agreement with Dr. Stokes in regard to what constitutes radical operation in these cases, because it must be remembered that the lymphatics of the testicle follow, at least to a considerable extent, the spermatic vessels, that the lymph-nodes in which metastasis takes place are those lying immediately below the kidney. If we are to make any considerable attempt at eradicating the glandular involvement we must make an incision which exposes the kidney. It has never seemed to me that this was worth while. I do not believe it to be possible to remove those glands in a way to be of benefit to the patient. The removal of the testicle, with the cord, at a point high up in the inguinal canal, is as much as we can do with advantage.

Dr. Arthur Dean Bevan, Chicago: In discussing any case of tuberculosis one should remember that almost all of these cases are secondary. Tuberculosis of the epididymis is a secondary affair almost invariably, just as is tuberculosis of the kidney in a certain sense, in that they are hematogenous infections and that there is almost invariably some primary lymphatic tuberculosis or tonsillar tuberculosis in the body; when you handle a case of surgical tuberculosis, whether of the urinary tract or of the genital tract, you are not removing anything except the grossly involved structures no matter how radically you operate. If one carries that in mind I think one must necessarily come to this conclusion, just as general surgeons do in handling tuberculosis of any part of the body, that in case you can remove a tuberculous focus, the overshadowing focus, by an operation that is justifiable and easily borne by the patient, it is a proper thing to do, because the patient then has a much better chance of cleaning up the remnants of the tuberculous process that always remain.

In genital tuberculosis the proper thing to do in the great majority of cases would be a simple operation; removal of the epididymis and that part of the vas that is also grossly involved. I hardly think that it is good routine to follow the vas down to the brim of the pelvis, unless the vas is greatly involved, and if it is involved so far down as that, one may be pretty sure that the seminal vesicles and prostate are also involved. If a minor operation, without any hardship to the patient, would clear up the focus, that should be done. When that is done, the patient should be given the general hygienic treatment that is given in cases of lung tuberculosis, and possibly, of course, tuberculin.

I never have cured permanently a single patient with malignant tumor of the testicle. If you have a suspicious tumor of the testicle and you do not know whether it is malignant or not, there is just one thing to do, and that is to make an exploratory incision. I have found that some of the growths that I supposed were malignant were nothing more than compound hydroceles with thick walls. I have found some of them to be gummas. The possibility of permanent cure in malignant disease of the testicle is so small that we are not warranted in removing suspicious tumors which may be benign. There is little danger in making an exploratory operation in malignant tumors. It is perfectly rational and scientific to take out a section of tissue, examine it with the greatest care, and then, if it is malignant, do a radical operation.

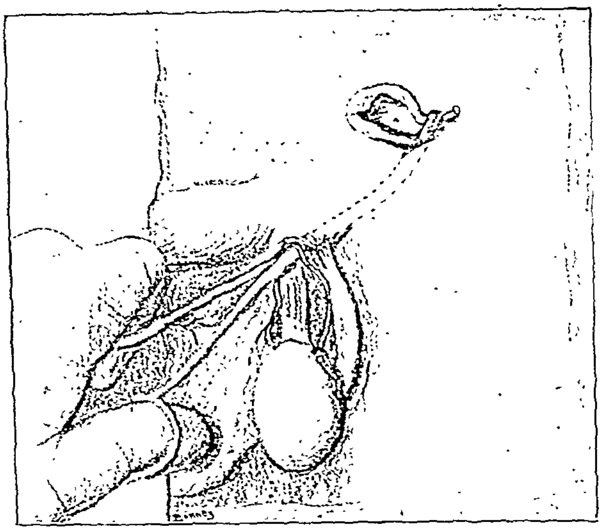

Fig. 1.—Vas held in curved clamp which has been passed up into the inguinal canal and is making its exit through a small incision opposite the internal inguinal ring.

**Dr. V. D. Lespinasse**, Chicago: I am heartily in accord with the operative technic which Dr. Cabot has described. I only wish to call attention to some of its difficulties. The first one of these is hemorrhage. I have had one or two cases in which it has been rather difficult to stop the hemorrhage from the testicle after the epididymis has been removed. Hemostasis must be done with a great deal of care, and it has been my practice, after I have stopped the bleeding, to put on a compression bandage at once. I should like to ask Dr. Cabot if, after treating the vas as he does and cutting it off down in the pelvis, he has ever had a transference to the pelvis of the mass that we sometimes get in the groin? It seems to me that this mass might possibly occur there and cause more trouble than if it occurred in the scrotum. It has been my practice to cut the vas off and inject it with phenol (carbolic acid).

**Dr. Hugh H. Young**, Baltimore: These tumors certainly are the most remarkable and bizarre type of tumors that we have. It seems to me that early operation is unquestionably the thing. I can remember a number of patients who have been treated unsuccessfully with iodid of potassium for months, and ultimately have come for operation when it was too late. It has been my habit to attack these tumors from above, that is, going in on the cord and dividing the veins and other structures of the cord high up, before there is any traumatism of the testicle, from which the veins might become infected, causing metastasis. In many cases of malignant disease it is important to get above the disease in order to prevent metastasis from traumatism and pressure at operation.

Dr. Cabot brought up a subject that has not been dealt with in a comprehensive way for several years. It seems that tuberculosis of the globus major of the epididymis is almost always primary and probably comes through the venous supply. The involvement of the second side generally occurs, just as a gonococcus infection occurs, in the globus minor, sometimes as a fulminating inflammation, with much pain, swelling, redness and tenderness, simulating a severe gonorrheal infection. It would seem to me, therefore, that, in some cases at least, when the second side becomes involved the disease has traveled up and involved the prostate and seminal vesicles and then gone down through the vas, involving the second side, just as the gonococcus does. Undoubtedly epididymectomy is the operation of choice and every effort should be made to preserve at least a portion of one testicle.

I had one case eight years ago in which I followed the vas far up into the groin and divided it at the pelvic brim. The patient had a tuberculous peritonitis afterward. That case has rather deterred me from following the vas so far. I usually follow the vas up to the groin and then inject iodoformized oil. It is generally possible to get from 15 to 20 c.c. of oil down into the vas deferens, and probably to fill the seminal vesicle and the posterior urethra with it. This method has been used in our clinic for years with good results. The trouble with the earlier operation was that it was too radical. The trouble with the operation through the perineum was that the urethra was invaded and a urinary fistula remained. I believe that if we do come to an operative treatment of these severe cases of tuberculosis of the prostate and seminal vesicles, it will be an operation possibly removing more or less completely the tuberculous seminal vesicles and the lateral lobes of the prostate, but not penetrating the urinary tract.

**Dr. S. A. Mahoney**, Holyoke, Mass.: Relative to Dr. Cabot's trouble in the region of the external inguinal ring when he has simply divided the vas deferens at the opening, I have had that same experience in a small number of cases. Patients have returned to me from one to two months after the scrotum and testicle have healed perfectly with a disagreeable swelling and inflammation in the region of the external ring.

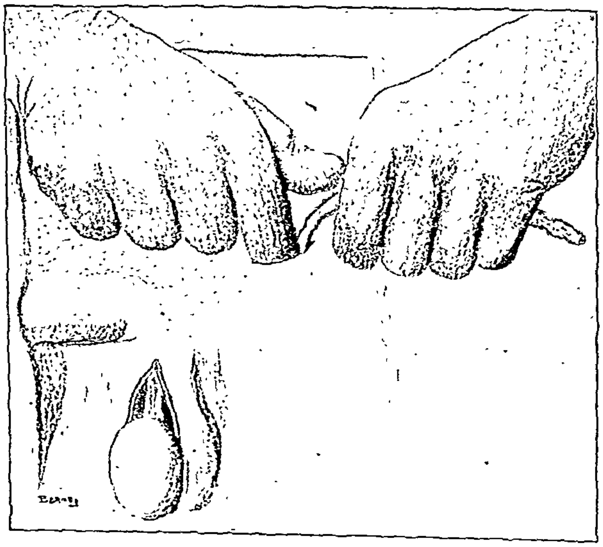

Fig. 2.—Tension is made on the vas by the operator's left hand, while with his right index-finger in the inguinal incision he frees the vas over the pelvic brim.

**Dr. A. C. Stokes**, Omaha: It is practically impossible to make a clinical diagnosis of tumor of the testicle. The trouble has been to differentiate tumors from gummas, as Dr. Cabot has brought out.

On account of metastasis, I am inclined to believe with Dr. Bloodgood and others that exploratory incision into malignant tumors is not a good thing, especially in the testicle.

Metastasis often follows rapidly on an incision. It seems best to open the scrotum and then, if we should find an infiltrated hydrocele, the procedure is simple, but if we think that the growth is malignant we can make a frozen section and determine its nature at once: if it is malignant, we must take out all the glands as far as possible retroperitoneally.

Dr. Hugh Cabot, Boston: In regard to the management of the vas the point to be remembered is that the involvement of the vesicle and the prostate bears no relation whatever to the involvement of the vas. The process does not reach the vesicle and prostate by continuity, but, as I believe, by the lymphatics. It is not easy to determine the amount of involvement of the vas. You will often find nodules separated by two or three inches. The infection has stopped at certain places along the lymphatics and invaded the vas. I have been disagreeably surprised to find little nodules along the vas far above the point I had suspected, and it has seemed to me that the removal of the accessible portions of the vas is important. I doubt whether the injection of any substance through the vas has any particular effect on tuberculosis of the vesicle, because the process is not in the lumen but in the wall. The vesicle is involved from without, not from within. Certain it is that the removal of the vas in this way—we have been doing it for years—has left the patients much more comfortable, and I must see something other than theoretic reasons for changing my views.

The involvement of the second side is an interesting problem. I do not believe that there is any reason for regarding it as an involvement by continuity. I believe that the process reaches the prostate and the vesicle by the lymphatics, and that it reaches the second epididymis by the lymphatics or by the blood-stream. I do not believe that it walks up one side and down the other any more than I believe that this is the common method of transference of the gonococcus. We want to remember that Keyes' statistics and other large statistics, including a series of one hundred cases by Dr. Barney, show that involvement of the second side must be expected in 50 per cent. of the cases within two years. This might as well be taken into consideration from the first.

It has seemed clear that the leaving of the testicle is important. The testicle is valuable for three reasons: In the first place, it forms spermatozoa. We must recognize at once that those patients with involvement of one epididymis in tuberculosis are sterile as demonstrated by Keyes, Barney and by foreign observers, so that, so far as the spermatogenic function is concerned, we may drop it; but nobody to-day, I think, doubts the presence and the value of the internal secretion of the testicle. The third factor in regard to the testicle is its psychic value to the patient, apart from the internal secretion. The average man is much interested in his testicle, and for what seems to me perfectly sufficient reasons. Now what is the logic of the old method of orchidectomy? If you begin by taking out the first testicle, the patient is liable to put a hard problem up to you or somebody else by coming around with the other testicle involved so that you ought to take that out, and then he refuses to have it done. The logical thing is to leave what is there accessible, not seriously damaged, and take your chances on the other side.

---

Dust.—There is no substance on the face of the earth which does not enter into the composition of dust. In the home there are particles of furniture, clothing, foodstuffs, animal and vegetable matter, bacteria, particles of wall-papers, plaster, iron and other metals, carpets, rugs, books and everything in the process of nature's decay contributing its quota of dust. In the street all the foregoing are in evidence in the dust, also particles of steel and iron from the wearing of wagon-wheels and horseshoes, gold, sand, stone, hair, excreta, clay, minerals of every kind, bacteria, leather skins, plant life, animal life of many kinds—in fact, there is nothing imaginable which does not contribute to the dust of the earth, and many thousands of dust particles may be found in every cubic inch of the air we breath.—*Bull. Winnipeg Dept. Health.*

# CHRONIC STENOSING GASTRITIS *

HORACE W. SOPER, M.D.

ST. LOUIS

Chronic stenosing gastritis was recognized and described by both Andral[1] and Cruveilhier[2] in 1829. Since that date much discussion has ensued among pathologists as to the nature of the process, some maintaining that it is always a malignant or cancerous condition, others that a benign inflammatory stenosis may occur. Among the synonyms found are "chronic interstitial gastritis," "sclerosis of the stomach," fibroid induration," "hypertrophic stenosis of the pylorus," "cirhosis of the stomach" or "linitis plastica." The term "Schrumpfmagen" has been most commonly employed in Germany. Von Sury[3] distinguishes two forms, a carcinomatous and a simple inflammatory type. He defines the latter as a primary increase in the thickness of the stomach wall, produced by a connective-tissue hyperplasia involving the submucosa and subserosa, the capacity of the stomach being diminished by a secondary contraction of the newly formed connective tissue. In a very exhaustive and critical review of the literature, he concludes that the etiologic factors involved in the simple inflammatory type are round ulcer, gastritis phlegmonosa, chronic gastritis, chemical irritants, syphilis, polyserositis occurring in passive congestion in diseases of the liver, heart and lungs, chronic peritonitis, primary *Zuckergussleber* of Curschmann, and trauma.

Congenital hypertrophic pyloric stenosis is not considered here, inasmuch as this condition appears to have no relationship to the etiology of the benign stenosis occurring in adults.

While one cannot deny that the before-mentioned etiologic factors can result in the pathologic process known as simple inflammatory contracted stomach, or *Schrumpfmagen*, nevertheless for clinical reasons it would seem best to restrict the term "chronic stenosing gastritis" to those cases in which a long-continued gastritis has been the causal factor. I shall therefore consider only this simple form, in which the stomach alone is involved. A few have combated this view, notably Charles F. Martin,[4] who takes the position that chronic gastritis has no etiologic relationship to simple contracted stomach. He agrees with Brinton and terms the process linitis plastica, or cirrhosis of the stomach. He considers it due to an overgrowth of connective tissue, such as may occur in any part of the body, caused by unknown irritants.

Von Sury shows that all the careful modern histologic studies of cases reveal the fact that the mucosa as well as the submucosa and subserosa is involved in the inflammatory process, and that pathologically it must be considered as a true gastritis. He particularly emphasizes that the passive congestion occurring in heart failure is a distinct etiologic factor in producing a polyserositis involving the stomach and other abdominal organs, and that Curschmann's *Zuckergussleber* is allied to this process. It is clear that clinically we may exclude cases of this class as well as general chronic hyperplastic peritonitis. Hemmeter refers to the confusion existing in the literature and points out that many cases of ulcer cicatrices have been reported under the term chronic stenosing gastritis. It is obvious that trauma cannot be considered as an etiologic agent.

The cases of Hemmeter and Stokes,[5] Einhorn,[6] Reignier,[7] Gross[8] and others make it clear that syphilis may produce contraction and stenosis of the stomach, which is extremely difficult to differentiate from the condition caused by chronic gastritis. It is probably better, however, to consider this form as only one of the several manifestations of gastric syphilis.

Primary chronic stenosing gastritis, therefore, always results from a long-continued, chronic inflammation. The hyperplasia affects chiefly the pyloric half of the stomach and ultimately results in a diminution in the lumen as well as a narrowing of the pylorus.

The symptomatology is that usually observed in the progress of an ordinary chronic gastritis, except that signs of stenosis gradually appear. In late cases, hydrochloric acid is absent and lactic acid and Oppler-Boas bacilli are often present. Nothnagel mentions that a smooth indistinct resistance may often be palpated. The differentiation from diffuse scirrhus carcinoma may be difficult, as both may give the same stomach content findings. Occult blood is often absent in this type of carcinoma, as well as in chronic stenosing gastritis. The anamnesis and the course of the disease are the determining factors. Recently S. Jonas[9] has asserted that the Roentgen ray will show an insufficient or gaping pylorus in diffuse scirrhus carcinoma.

The stenosis caused by ulcer scar is totally different in clinical manifestations. The presence of hydrochloric acid in the fasting stomach should alone be sufficient to differentiate.

In the vast majority of cases, the diagnosis has been made at necropsy. Even here, difficulties are encountered. Von Sury demonstrates that the endothelial cells of the lymph vessels may assume a peculiar cuboidal form which closely resembles epithelial cells. On the other hand, the epithelial cells may be so few in number as to escape detection in true diffuse carcinoma.

Excluding syphilis and doubtful cases, such as ulcer scar, diffuse carcinoma, etc., the writer limits the number of genuine cases of chronic stenosing gastritis to twenty-nine.

Tilger[10] tabulates twenty-three cases; of this number, four occurred between the ages of 20 to 30, seven between 30 and 40, six between 40 and 50, two between 50 and 60, two between 60 and 70 and two over 70. Boas'[11] three patients were aged 32, 43 and 47, Hemmeter's[12] four patients 23, 28, 36 and 38 years.

### REPORT OF CASE

*Patient.*—A farmer, aged 36, good family history, came under my observation in April, 1910. He had an attack of acute articular rheumatism at age of 14. He uses no tobacco, but had been a steady moderate drinker since the age of 20, averaging three glasses of whisky a day. During the past year he had abstained entirely from alcohol. No history of syphilis. His stomach trouble began twelve years ago; at first, only discomfort and eructations of gas after eating; eventually, nausea and vomiting appeared; never any pain. These symptoms with the usual remissions and exacerbations have persisted since. Six years ago a test-breakfast was given and he was told that he had no hydrochloric acid in the stomach contents. For the past year his appetite has failed, and he has been obliged to resort to liquid and semisolid foods in small quantities. Solid foods as well as large quantities of liquids always produce nausea and vomiting. His strength has failed and he is no longer able to do his work.

*Examination.*—He is a sparely built man, 5 feet 9½ inches in height, weight 117 pounds. Maximum weight twelve years ago, 135 pounds. He is somewhat anemic looking. Chest reveals nothing abnormal. Abdomen, rather narrow epigastric angle, very little fat, strong musculature. The entire epigastrium is tender to pressure. Tendon reflexes normal. Pupils respond well to light and accommodation. A Ewald-Boas test-breakfast, 60 c.c. Chyme, bad. Much stomach mucus. No hydrochloric acid. Total acidity 8. No rennin, no lactic acid, no long bacilli. Fasting stomach contents, 30 c.c. of yellow turbid liquid; no fetor; no food residue; no hydrochloric or lactic acid. Microscopically there are many pus-cells and squamous epithelial cells. The feces on vegetable diet show no occult blood. Schmidt's test-diet shows a good utilization of the starches, fats and proteins. Blood: Hemoglobin 60 per cent. No leukocytosis. Red-cells 3,500,000, well filled. No poikilocytosis. Wassermann reaction negative.

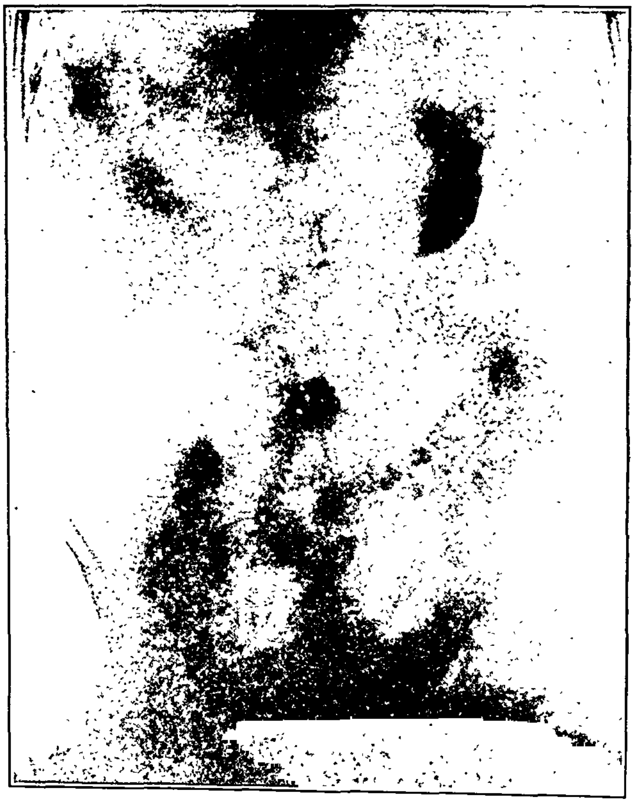

Fig. 1.—View of gastro-intestinal tract, taken immediately after the ingestion of 500 c.c. of bismuth and fermented milk. Note the extensive dissemination in the small intestine. This and the following radiograph were taken by Dr. R. D. Carman.

Urinalysis: The urine is scanty, but otherwise normal.

*Treatment.*—He was dieted carefully, but grew progressively worse and was confined to bed. Even liquid foods in small quantities were vomited. In June, pyloric stenosis was suspected as the fasting stomach showed small quantities of stagnating food remnants. Lavage produced considerable relief. Roentgenograms could not be procured as the patient could not retain the bismuth meal. In July his weight was reduced to 102 pounds. Lactic acid and Oppler-Boas bacilli were frequently found in the stomach contents. The pus increased in quantity. The glycyltryptophan test was negative. Hemoglobin 35 per cent. The blood-smear showed no signs of pernicious anemia.

August 3: Operation by Dr. Willard Bartlett. The stomach was found to be small and presented a peculiar feeling of resistance. The serosa was thin and smooth, the pyloric region was particularly hard but was smooth and uniform. Anterior gastrojejunostomy was done. The stomach wall was ½ inch in thickness and was difficult to cut through. The incised surface presented a white, almost cartilaginous appearance. The mucosa was thin and anemic looking. The pylorus would not admit the end of the finger. Considerable difficulty was experienced in applying the sutures because of the toughness of the stomach wall. The patient made a good recovery.

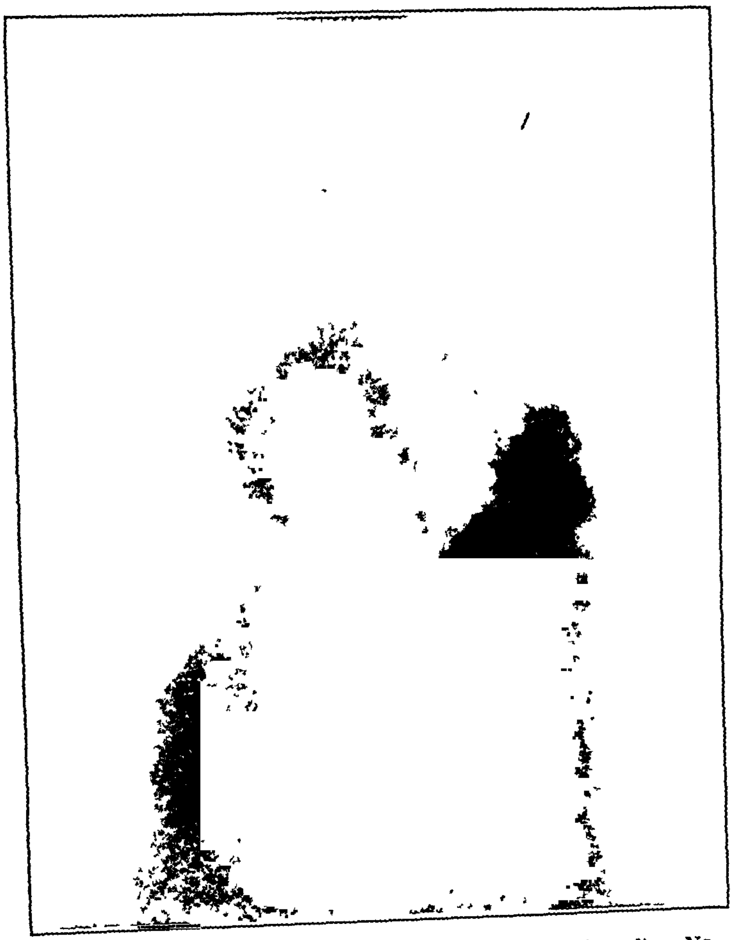

Fig 2.—Same subject: picture taken immediately after No. 1. Very little of the bismuth mixture remains in the stomach

Sept. 9, 1910: Weight, 111 pounds. Able to take liquid food without discomfort, no more than 4 ounces at a feeding. Roentgen fluoroscopy: The stomach is small, the bismuth and fermented milk mixture is swallowed slowly and passes at once out of the gastro-enterostomy stoma, so that it is impossible to obtain a view of the stomach contour.

Dec. 20, 1910: Improvement continued, weight 125 pounds. The patient is able to take semisolids and 8 ounces of liquids at a feeding. Fasting stomach contents, 20 c.c. bile colored liquid, no food residue, no hydrochloric or lactic acid, no pus cells, no long bacilli.

June 13, 1911: Weight 130 pounds. Patient takes larger quantities of foods, but cannot tolerate meats. Test breakfast. 40 c.c. Chyme bad, much stomach mucus, slightly tinged with bile, no hydrochloric or lactic acid, no long bacilli. Fasting stomach contents, 15 c.c. bile-colored liquid, no hydrochloric acid, no food residue, no pus.

September, 1912: Weight 130 pounds. Stomach content findings same as last time. Hemoglobin 75 per cent. Roentgen fluoroscopy reveals stomach dimensions after rapidly drinking 1 pint of the bismuth suspension to be: length from cardia to lower pole 6 inches; width near cardia, 3 inches; width near pylorus, 1 inch. The food passes very rapidly out of the gastro-intestinal stoma without any intermittence. Very small masses pass intermittently out of the pylorus. There is no peristaltic wave visible; the stomach moves up and down when food is introduced, making an excursion of about 1 inch, not synchronous with respiration. The roentgenograms were taken as rapidly as possible, Figure 1 immediately after the bismuth suspension was drunk, and Figure 2 as soon as a second plate could be put in position.

The rapid dissemination of the bismuth in the small intestine is clearly shown. This is probably due to the gaping of the incision in the thick wall of the stomach.

The patient continues in excellent health, and considering the history of the case and the course of the disease subsequent to the operation, the possibility of carcinoma is probably not to be considered now.

The roentgenograms were taken by Dr. R. D. Carman.

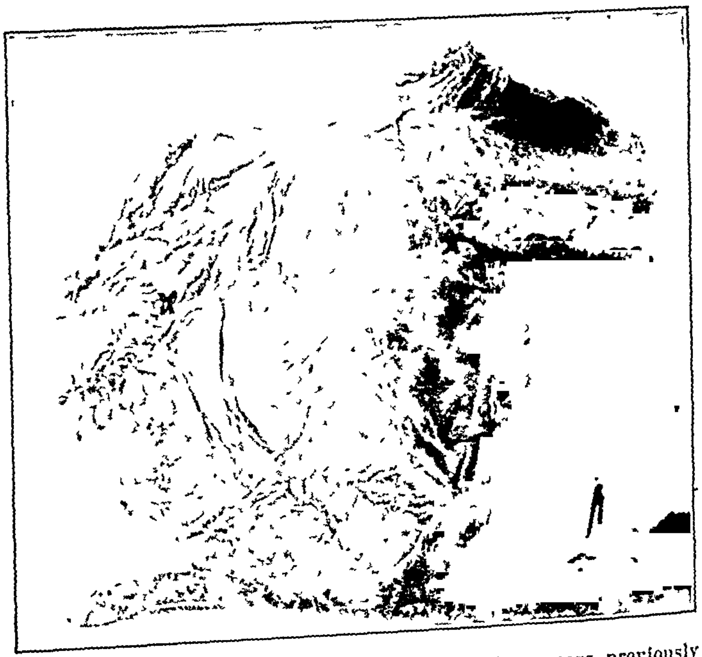
625-632 Metropolitan Building.

## BLADDER SUTURE FOUR YEARS AFTER OPERATION

James R. Judd, M.D., Honolulu, T. H.

About three years ago[1] I described a case of intraperitoneal rupture of the urinary bladder in which operation was performed seventy-seven hours after the receipt of injury. The patient made a good recovery and was entirely free from any bladder symptoms subsequently.

Four years after the operation the man died of pneumonia and the bladder was removed at the post-mortem examination. There were no adhesions along the suture line. The scar of the rupture is represented by a thin line 2¼ inches in length. At the time of the operation the rent easily admitted four fingers. An additional point of interest is the fact that a careful search failed to reveal any trace of the continuous silk suture used at the operation.



Bladder, showing scar of operation done four years previously for intraperitoneal rupture. The scar extends from points x to x.

**Coal-Mine Accidents.**—The risk of coal mining is greatest during the winter months, when the liability of serious mine explosions is increased by the drying of the mines through the entrance of air below the temperature of the workings. —Horton, *Bull. Bureau of Mines.*

## A CASE OF DISLOCATION OF PROXIMAL PHALANX OF GREAT TOE

P. G. Skillern, Jr., M.D., Philadelphia

P. W., male, white, laborer, aged 56, reported at the surgical outpatient department of the University Hospital, service of Dr. B. A. Thomas, May 28, 1913, with the history of having been kicked by a horse nine weeks previously, and of having been treated at another hospital for an injury to the left knee. He now complains of pain in great toe. Examination reveals fixation of great toe in extreme extension and crepitation at metatarsophalangeal joint. The roentgenogram (Fig. 1) shows displacement of proximal phalanx of hallux onto the dorsum of the head of its metatarsal. The anteroposterior view (Fig. 2) is of interest in showing concomitant displacement of the sesamoids from the plantar aspect to each side of the joint. Under nitrous oxid reduction was attempted by means of Levis' apparatus, but owing to lacerations of the skin this method was abandoned. A trial was next made of the method proposed by Dr. Crosby of New Hampshire in 1826, for reducing dislocations of the thumb, which was so well spoken of by the elder Gross. The toe was raised perpendicularly and strong pressure applied against the base of the phalanx, so as to push it from behind forward and from above downward. Reduction was maintained by strapping the hallux down on a plantar splint, which was applied after the method described by Cotton.

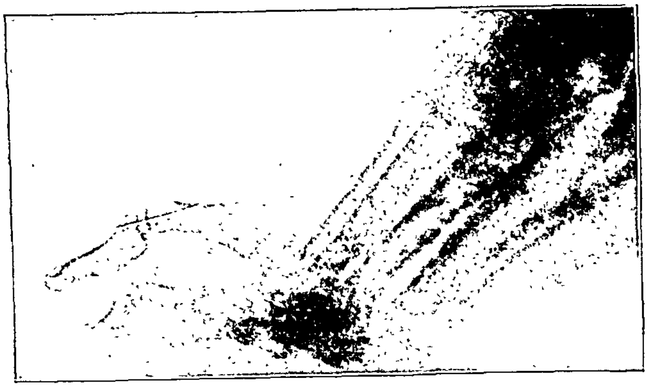

Fig. 1.—Base of proximal phalanx of great toe resting on dorsum of head of first metatarsal. Note plane occupied by sesamoid. Lateral view.

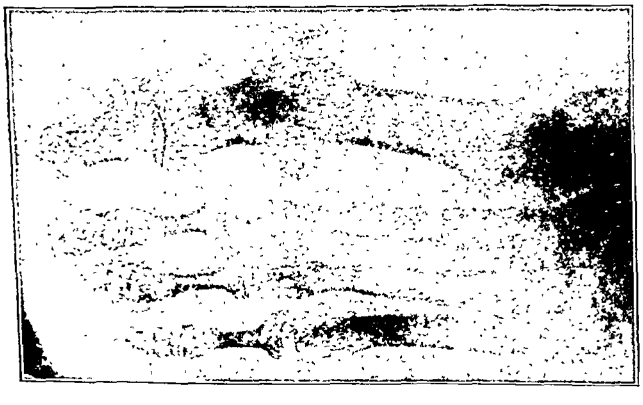

Fig. 2.—Note shortening of hallux and diastasis of sesamoids so as to embrace the joint. Anteroposterior view.

This injury was evidently overlooked at the other hospital, and the deformity must have been greatly increased during the intervening nine weeks by contraction of the extensor hallucis proprius.

That the injury is rare is attested by the statement of Dr. Henry K. Pancoast, who took the roentgenogram, and also by the fact that Gross[1] had seen but two cases. Of twenty-two cases of luxation of the proximal phalanges of the toes Malgaigne states that nineteen were of the great toe. In Holmes' "System of Surgery,"[2] the analogy between this luxation and that of the corresponding phalanx of the thumb is pointed out, as well as a similar difficulty in reduction. In four out of ten cases noted by Malgaigne[3] the reduction could not be accomplished. In accounting for this difficulty of reduction it is of interest in connection with our case to note the statement of Gross[1] that "it depends probably on the manner in which the adductor muscle and the sesamoid bones are dragged by the displaced phalanx backward over the extremity of the metatarsal." The roentgenograms, especially Figure 2, show clearly the relative positions of the sesamoids, and that they in no way interfere with reduction, not in my case at least.

241 South Thirteenth Street.

## CASE OF FOREIGN BODY IN THE RECTUM

Frank M. Conlin, M.D., Omaha

On the morning of Aug. 11, 1913, I was called by the proprietor of a hotel to see one of his employees, a dishwasher, who, he said, had been sick since the day before. The patient, a Dane, aged 68, stated that he had fallen on a cup about two weeks before and cut himself. He complained of severe pain in the left iliac and hypogastric region. He gave no history of vomiting, but stated that his bowels had moved the day before and that he had urinated that morning. His temperature was 99 and his pulse 80. There was blood on the bed. Examination showed a mass in the left iliac region.

I took him to the hospital, and on further examination found blood coming from the rectum, and a deep laceration through the mucous membrane and the sphincter muscle in its posterior aspect. Examination under anesthesia disclosed a china cup in two pieces, the smaller piece being about one-third of the side of the cup.

The cup, being firmly held with a pair of pliers, was broken into eight pieces with short quick raps of the hammer on a cold-chisel, and the pieces removed.

I irrigated the area with normal salt solution and could find no perforations. Examination of the cut surface of the sphincter showed an old wound covered with granulations, the bottom made up of fibrous tissue. The sphincter muscle and mucous membrane were sewed later. The man made an uneventful recovery, leaving the hospital in nine days, seemingly with good control of the sphincter. I am convinced that the patient had been accustomed to putting foreign bodies in the rectum for some time to satisfy an abnormal sexual appetite, and that at this time he inserted the cup, when, on account of the spasm of the sphincter at the time of the orgasm, the cup was forced up inside. He evidently had made an attempt to remove it afterward, which would account for its being broken.

The cup, a thick one without handles, measured 82.5 mm. (3¼ inches) in height, 90.5 mm. (3 9/16 inches) in diameter across the top, 51 mm. (2 inches) across the bottom and 1 cm. (6/16 inch) thick.

Kelsey mentions a specimen in the Museum of Anatomy and Pathology in Copenhagen, which was introduced by a patient in an attempt to prevent a prolapsus. It is a long, oval, flat stone about 6¾ inches long, 2½ inches wide, 1½ inches thick and weighs nearly 2 pounds. The stone was extracted by a surgeon, Frantz Dyhr, in 1756.

In the Surgical History of the War of the Rebellion, II, p. 322, there is mentioned an operation performed on a sailor who had introduced into the rectum a stone 5½ inches long by 3 inches wide. The colon was perforated, and the stone was removed from the peritoneal cavity by an incision near the umbilicus.

# *New Instruments and Suggestions*

## NEW KIDNEY FORCEPS

Ferdinand C. Walsh, M.D., San Antonio, Tex.

Those doing kidney work are well aware of the difficulty frequently encountered in the delivery of the kidney preliminary to nephrotomy, nephrectomy or operative procedure on the pelvis or upper portion of the ureter. Tardy delivery is often the main factor in prolonging an operation which otherwise would occupy but a few minutes.

So far as I am aware, all forms of kidney forceps now on the market, when fitted to the kidney, possess the drawback of exerting undue pressure on the renal substance, thereby frequently causing irreparable damage to the organ, or through hemorrhage, from tearing the friable kidney substance, causing the operator much annoyance and extra repair work.

The forceps which I devised, and which I have found serviceable in overcoming those difficulties, as will be seen from the accompanying illustrations, is of a modified obstetric pattern, fitted with a Hodge lock. The opening between the tips of the blades allows a firm grasp of the kidney with non-interference from the pedicle which rides free between. In delivering the kidney, the traction exerted in no way causes compression of the kidney substance, as the blades lock loosely over the kidney, and all force is directed from above downward on the pedicle itself. When the kidney has been exposed, after stripping off its fatty capsule, the anterior blade is first introduced, in order that no damage may be done to the peritoneum. With a finger behind the kidney to locate the pedicle, the blade is carefully put in position, the pedicle being allowed to slip between its tips. The opposing blade is placed in a like manner behind. With the blades locked, gentle traction is made, and in this manner adhesions become taut, and may easily be stripped, or, if deemed expedient, ligated and cut. After delivery, should it be desired to do a nephrotomy or pyelotomy, the handle of the forceps is turned directly backward, the upper blade removed and the lower blade thrust forward, thus allowing the kidney to ride free above the incision, the blades projecting well beyond both edges of the wound, preventing the organ from dropping back into the cavity.

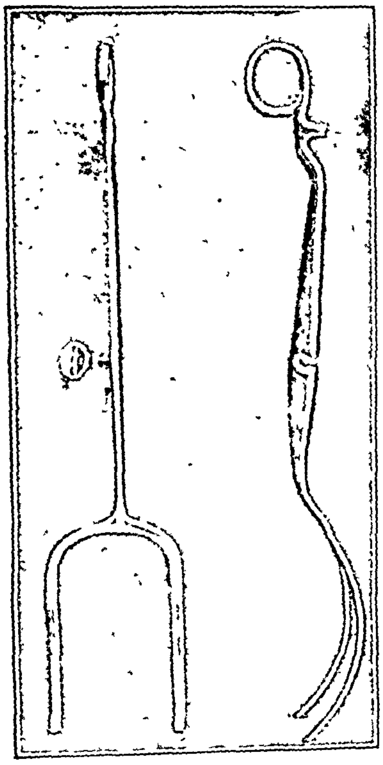

Fig. 1.—Walsh kidney forceps; posterior and side view.

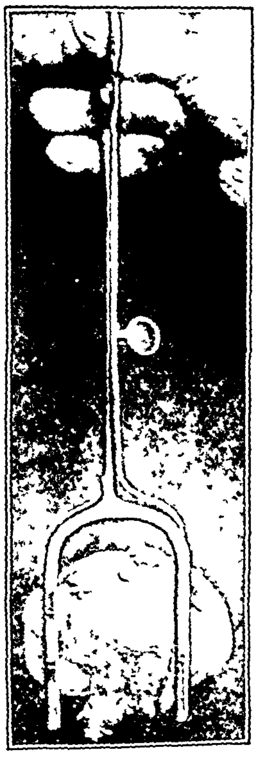

Fig. 2.—Walsh forceps in position on kidney. Note wide space between tines.

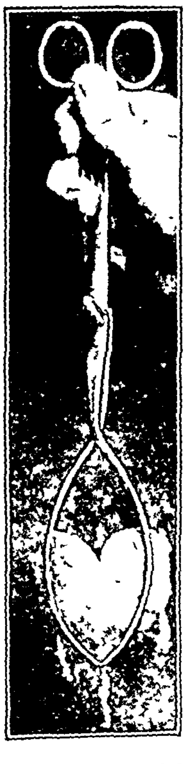

Fig. 3.—Walsh forceps on kidney; side view.

The width between the tines for the reception of the pedicle is 1⅝ inches. The convex blades fully closed measure in their long axis 4½ inches, while the transverse diameter is 2 inches. The kidney used in the illustration is an unusually small one.

Moore Building.

## A SIMPLIFIED COLORIMETER

### SPECIALLY ADAPTED FOR TESTING THE EXCRETION OF PHENOLSULPHONEPHTHALEIN IN THE FUNCTIONAL KIDNEY TEST *

James I. Armstrong, M.D., Pittsburgh, Pa.

Finding the less expensive colorimeters in general use for the kidney functional test (as popularized by Rowntree and Geraghty) rather unsatisfactory, I devised the instrument here described. Figure 1 shows the colorimeter closed, with an opening in the anterior surface giving a view of the bottles in position. Figure 2 shows the two compartments with closed sides and posterior surface of opal glass. A two-candlepower frosted globe is used for illumination.

The standard solution is made by diluting 6 mg. of phenolsulphonephthalein with 1 liter of distilled water and adding sufficient 25 per cent. sodium hydroxid solution to elicit the maximum color. The small bottle is filled with the standard solution, hermetically sealed and labeled 100 per cent. Serial dilutions are now made of 95, 90, 85 per cent., etc. The bottles are to be kept in a dark case and refilled when necessary. The test is carried on in the usual manner. The urine is diluted to 1 liter with distilled water, to which a 25 per cent. solution of sodium hydroxid is added to give a maximum color reaction, and a small quantity filtered. A bottle of this filtrate the same size as that of the standard solution is placed in one compartment, and the standard solution which matches this in the other compartment and the percentage excreted, read directly.

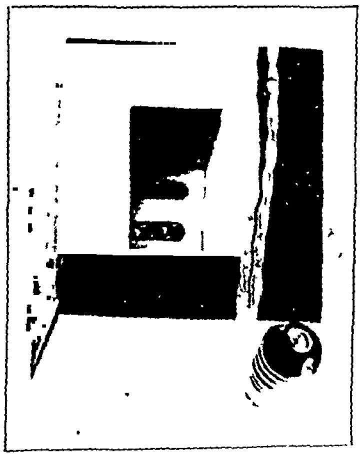

Fig. 1.—Colorimeter closed, showing bottles from anterior.

The advantages which this colorimeter has over others are: (1) its accuracy, simplicity and cheapness; (2) its uniform light at all times, (3) and the ease with which it can be carried in case of emergency.

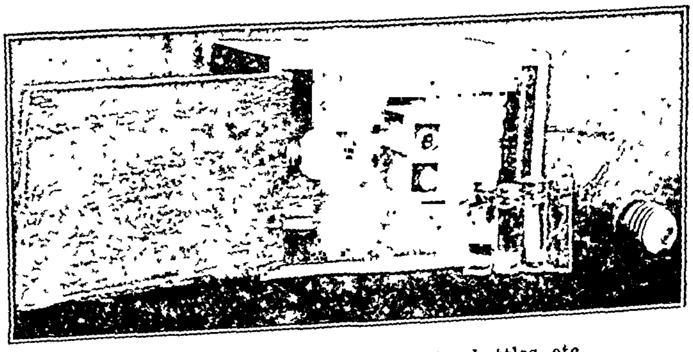

Fig. 2.—Bottles in position, extra bottles, etc.

The instrument can also be used for colorimetric determination of indican, creatinin, etc.

I wish to thank Dr. Fisher, who made the pictures for me.

476 South Rebecca Street.

## SOME INEXPENSIVE EQUIPMENT FOR THE PHYSIOLOGIC LABORATORY*

Clayton McPeek, M.D., Columbus, Ohio

Many instruments for the work in experimental physiology can be made in the laboratory at little cost. These pieces are sometimes more desirable than factory-purchased supplies and are an especial boon to schools with limited means.

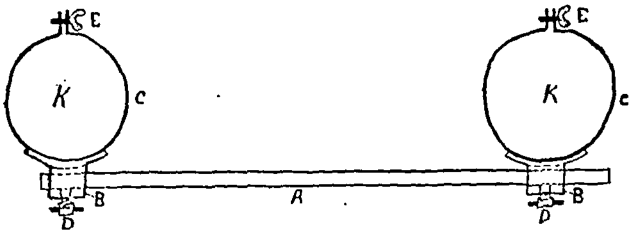

Fig. 1.—*A*, a steel bar ⅝ inch square and 4 feet long which passes through *B,B*; B,B, cast-iron pieces 1½ inches square posteriorly, with concave anterior surfaces for the attachment *C,C*; C,C are made from strap-iron 1¼ inches wide, ¼ inch thick and of sufficient length to encircle the base of the kymographs, *K,K*; *E,E*, thumb-screws for tightening of parts *C* around *K*; *D,D*, thumb-screws for adjustment of *B,B*, on *A*. The entire apparatus may be nickeled or given a coat of aluminum to prevent rusting.

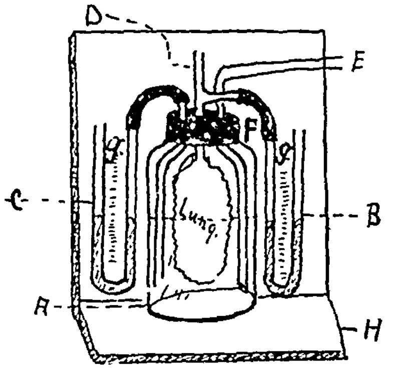

Fig. 2.—*A*, quart Mason jar the sides of which represent the chest wall; *F*, cap of the jar through which a large opening is made and a three-hole rubber stopper is placed; *D*, a T-tube, passing through the opening represents the trachea, to the lower end of which animal lungs are fastened; *B*, a mercury manometer connected to side branch of *D*, registering intrapulmonic pressure; *C*, a mercury manometer connected with space between lungs and bottle, registering interpleural pressure; *E*, a tube connected with a movable reservoir of water, raising or lowering of which will produce respiratory movements; *G,G*, millimeter scales for the exact determination of the changes; *H*, the support to which the entire apparatus is firmly secured. The lungs may be attached to the trachea by removing the cap of the jar and detaching the rubber connections to the manometers.

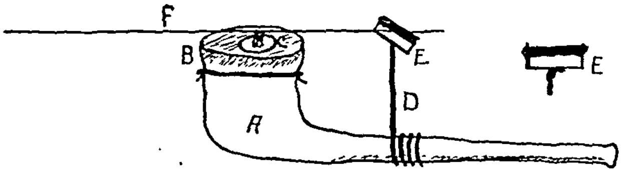

Fig. 3.—*A*, a clay pipe over the bowl of which a piece of rubber tissue is tied; *C*, a piece of cork or circular aluminum plate to which a lever, *F*, is lightly fastened. *D*, a piece of stiff wire encircling the stem; to its upper extremity *E* is soldered; *E*, a narrow strip of tin with ends bent at right angles; a rubber band is lightly stretched between the uprights. The lever, *F*, can be made from aluminum wire. It perforates the rubber band and rests on the cork, *C*.

An extension kymograph suitable for most purposes can be conveniently made by using two ordinary Harvard spring kymographs as a basis (Fig. 1). In operation one drum may be thrown out of gear or both kymographs run at uniform speed. In the laboratory any group of students having two small kymographs can make an extension kymograph. The cost of the entire apparatus is less than $4.

A scheme designed to show phases of respiration, respiratory pressures and their modifications can be made from a quart Mason jar (Fig. 2).

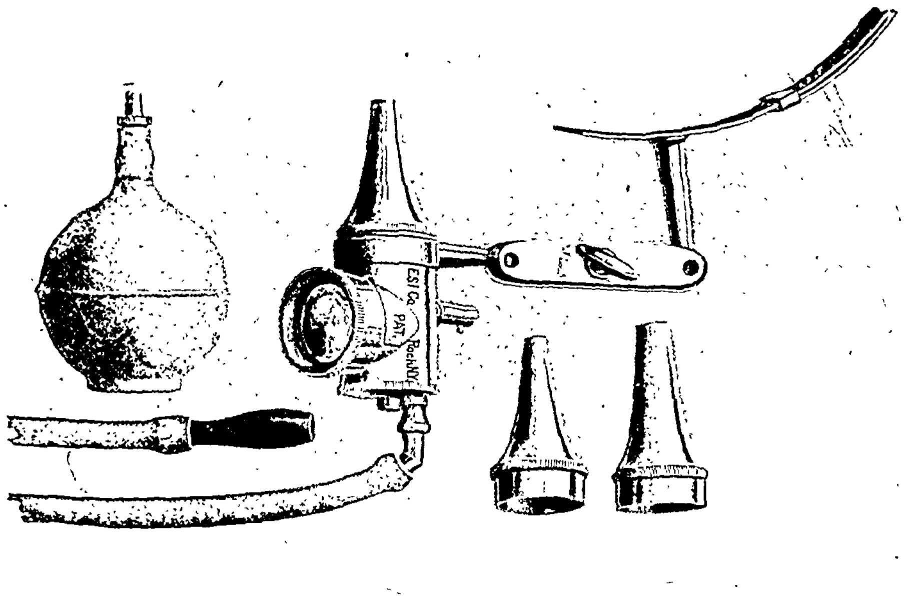
Ether cones suitable for animal work can be made from coarse meshed wire. Rectangular strips of wire are bent into suitable form and the ends soldered or wired together. Pieces of gauze are wound back and forth through the top as in the Allis inhaler. Canvas is sewed on the outside of the cone. If this is then covered with a melted mixture of white wax and paraffin a tight and ether-saving cone results.

An inexpensive tambour can be made from an ordinary clay or cob pipe (Fig. 3).

## THE MYRINGOSCOPE

George G. Carroll, M.D., Rochester, N. Y.

This instrument consists of a cylinder, one end of which is closed, and at the other end is fitted any one of three sizes of specula depending on the caliber of the external canal of the ear to be examined. On one side of the cylinder there is a round window with a magnifying lens, while inside and opposite the round window is a plain mirror at approximately an angle of 45 degrees. Inside the cylinder is attached a Tungsten lamp lighted by a 2½-volt dry battery, or it can be lighted by any other rheostat or controller desired. There is also attached to the cylinder an auscultation tube.



Myringoscope, with additional specula and bulb for converting instrument into a Siegel otoscope.

This instrument is held into the canal of the ear by an adjustable spring that fits laterally across the head. Before this instrument is used the external auditory canal should be thoroughly cleansed and an ear-piece of the proper size fitted, while at the same time any unusual characteristics of the external auditory canal can be noted, so that in using the myringoscope the best possible view may be had of the membrana tympani.

In using this myringoscope the spring is fitted across the head from the upper extremity of one ear to the other, the spring being bent first, if necessary, so that it will clasp the sides of the head firmly; then the clamp is bent down and lastly the speculum end of the instrument is swung into the external auditory canal, being pressed inward, upward and backward. It is also to be remembered that all movements are reversed. This instrument when in position gives the operator, while seated in front of his patient, a magnified view of the membrana tympani, while at the same time he has the advantage of the auscultation tube while inflating the tympanum. If a rubber band has previously been stretched around the tip of the ear-piece so as to make it fit as perfectly as possible to the external auditory canal, the instrument can, in a moment, be converted into a Siegel otoscope by attaching a rubber bulb to the auscultation tube at the ear-piece of the operator. Thus a comparison can be made between the excursions of the membrana tympani from inside pressure, and those of the Siegel otoscope compression and aspiration.

---

* From the Laboratory of Physiology of the Starling-Ohio Medical College.

So far as I know, the use of such an instrument is new for the study of the patency of the eustachian tube, inflation of the tympanum and the study of the excursion of the membrana tympani from inside air-pressure, as compared to the Siegel otoscope findings from without. Just what its efficiency will be in diagnostic work, time only can tell.

304 West Avenue.

## A NEW RETRACTOR FOR THE ABDOMINAL CONTENTS DURING PERITONEAL CLOSURE

M. B. Ahlborn, M.D., Wilkes-Barre, Pa.

This retractor was devised to take the place of the spoon and other appliances, which it becomes necessary to remove after the peritoneum is partially closed. The retractor, as will be seen, consists of five blades (or more if necessary, for increasing its field of retraction), a set-screw and a handle, all of which come apart by simply unscrewing a set-screw, thus rendering washing and sterilization extremely easy.

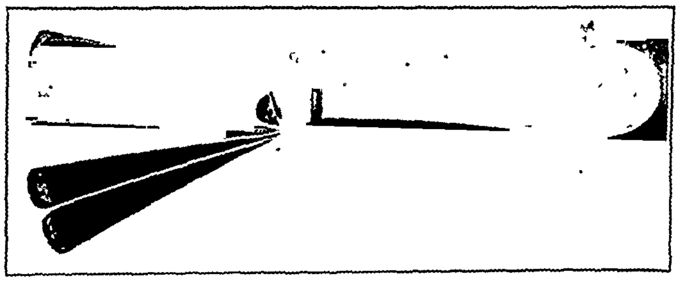


Figure 1.

For use the blades are attached to the handle and spread out like a fan with their edges just touching, this being done to prevent catching any abdominal contents when the retractor is closed and withdrawn at the end of the peritoneal suture (Fig. 1). The blades are set in this fan shape by screwing down the set-screw just tight enough to make them fairly rigid and they cannot become loose and drop off as the fifth or bottom blade has a very deep-seated thread to hold the screw, requiring a number of turns before the screw can be withdrawn from the blades.

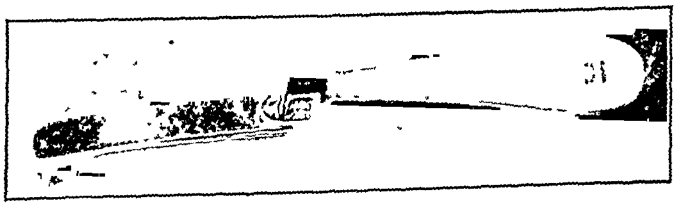

Figure 2

The retractor is placed in the wound and held by an assistant but not pressed down hard, as this causes the bowels or mesentery to slip up over the edges of any retractor. The weight of the instrument is sufficient to keep all abdominal contents back and the suturing of the peritoneum proceeds in the usual way, the peritoneum being picked up and held for suture by the usual clamps. When the wound is closed, except for the setting of the last stitch, the assistant simply gives a slight pull on the end of the retractor, when it closes as shown in Figure 2. The end of the closed blades can be retained in the angle of the wound until the passing of the last suture and formation of the knot, when it is removed and the knot tied.

The pictures show the instrument about one-third the actual size, it being 8 inches long and 3 inches across the outspread blades, when they are overlapping edge to edge. Of course the size of this retractor may be varied by altering the length and breadth of the blades.

It has been in practical use for some time and answers the purpose better than any I have yet seen devised.

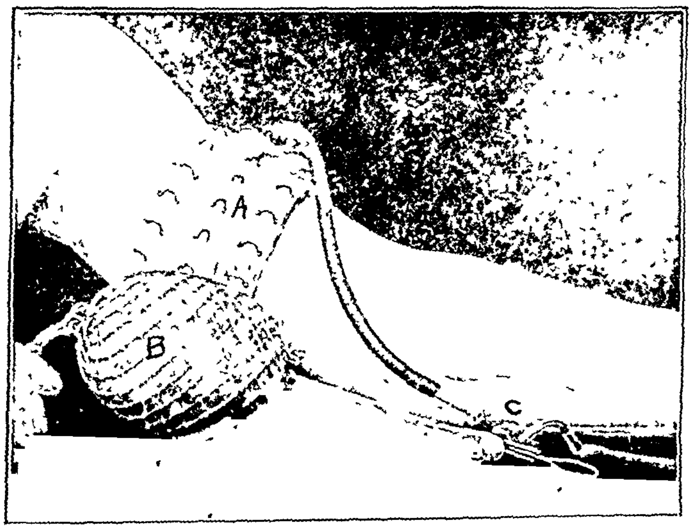
99 North Franklin Street.

## A SIMPLE TOURNIQUET USED IN GIVING SALVARSAN INTRAVENOUSLY

Thomas F. Laurie, M.D., Auburn, N. Y.

This simple and useful tourniquet consists of parts from a sphygmomanometer (Riva-Rocci). As may be seen from the illustration the parts used are the arm band, the inflating bulb and the relief cock, all connected by rubber tubing.

I present this more for those who are accustomed to giving salvarsan or neosalvarsan in their offices with no help except that which can be given by the patient. My experience has been that rubber tubing wears out very soon by repeated boiling and use; pressure has to be maintained for a longer period than is necessary with this apparatus and after the needle is inserted into the vein it is often folly to let go of it to release the tourniquet. I have also found that it is difficult for the patient to release it with one hand. Bandages and like materials are not good for the same reason and also on account of their inelasticity.



Tourniquet: A, arm band; B, inflating bulb; C, relief cock.

It is easy with this apparatus, after one has everything sterilized, including the hands, to request the patient just before inserting the needle into the vein, to inflate the arm band by means of the bulb. Then, when the fluid is ready to flow, it is a simple matter for the patient to release the pressure by pressing the relief-cock with his free hand.

15 Grover Street.

**Resistance of the Bladder to Tuberculosis.**—The bladder offers considerable resistance to attack by the tubercle bacillus, even when the mucous membrane is injured, as shown by experiments. Rovsing has demonstrated that tubercle bacilli, injected into the bladder and allowed to remain, often fail to produce a lesion. This explains how it is that in many cases of tuberculous nephritis the bladder remains healthy. But if other pyogenic organisms, and especially those which decompose urea, are present, the resisting power of the mucous membrane is greatly weakened, and secondary infection is almost certain to occur.—David Newman, M.D., *Glasgow Med. Jour.*, October, 1913.

## INFANTILE CONVULSIONS

Although the occurrence of convulsions is only a troublesome symptom of an underlying condition and, therefore, an entity, still the issue is of such importance that active means must many times be taken for their suppression, and prompt treatment must prevent, if possible, their recurrence. Prevention presupposes a diagnosis of the cause. The predisposition to convulsions which occurs in infants and young children is manifestly because of the ease with which their central nervous systems may be inordinately excited. This is shown by the fact that the conditions which frequently cause convulsions in young children may not cause them in an older child. About 75 to 80 per cent. of all infantile convulsions occur under the third year of life, and almost all (unless epileptic) occur before the child is five years old. Nearly 50 per cent. of all infantile convulsions occur during the first six months of life, nearly 25 per cent. before the end of the first year, not far from 25 per cent. during the second year, and in a few instances they occur as late as the fourth or fifth year.

Heredity seems to play a large part in the frequency of the convulsive seizures. The child of neurasthenic, hysteric and neurotic parents seems to be predisposed to convulsions. Healthy children from healthy parents rarely suffer convulsions, unless from some acute cause. If births are too frequent, the later children, even of healthy parents, are more or less predisposed to convulsions, because of their lessened vitality. The probability of convulsions in an artificially fed child is greater than it is in one who is breast-fed or who receives properly modified cow's milk.

Chronic, debilitating diseases, such as syphilis, tuberculosis, scurvy, anemia (whether from hemorrhages or from lack of nutrition), and rickets, especially, are frequent causes of infantile convulsions. They are also commonly caused by gastro-intestinal disturbance, perhaps an acute indigestion, with colic, vomiting, diarrhea, and more or less sudden absorption of toxins; or a chronic indigestion with a constant absorption of irritant products. In children affected by chronic intestinal disorder there is more or less emaciation and debility. In considering rickets as a cause, perhaps the underlying condition—some disturbance of one of the internal secreting glands, or improper food—may, through the debility so induced, result in convulsions, either from local irritation or toxic absorption. Convulsive movements such as slight muscle rigidities or mild laryngeal spasms often occur without intensification into a general convulsion. Sometimes this condition becomes a tetany.

Irritation of the gums during dentition is not as frequent a cause of convulsions as it once was thought to be, and the fact should be generally recognized that teething, as such, causes neither convulsions nor infantile diarrhea; but, if there be a swollen, red, edematous gum over a tooth that is about to erupt, it may be the cause of a convulsion, and should be lanced.

Intestinal worms probably do not cause infantile convulsions, but in producing active intestinal indigestion they promote the absorption of irritant toxins.

Besides the pain caused by inflamed gums, pain produced either by an inflammation in the ear, or by some other acute inflammation in the head, may be the cause of convulsions. Acute pain anywhere may cause such spasmodic crying and contractions of the muscles that congestion of the brain and a convulsion will result. Obstructive adenoids in the nasopharynx seem at times to be a cause of convulsions.

Irritation from a very much elongated and almost impervious prepuce has been a cause.

The statement has many times been made that the high fever incident to an acute infection frequently causes these diseases to be ushered in by a convulsion. While such convulsions in young children are not uncommon, still they can hardly be said to be frequent, and although they have been likened to the chill with which infections in older children and adults begin, they should not often be so considered. A convulsive onset in such acute infections as scarlet fever, diphtheria and measles is infrequent.

Acute lung congestion, as in pneumonia, may produce preliminary convulsions in very young children. Meningitis in any form presumptively induces convulsions somewhat more frequently in children than in adults.

Whooping-cough also may cause cerebral congestion and even meningeal hemorrhage sufficient to occasion convulsions, though a real apoplexy with paralysis from this disease has not occurred.

Convulsions that occur in a child soon after birth are often the result of instrumental delivery, and may be due to the abnormal pressure consequent on some displacement of the cranial bones. Convulsions from this cause may be frequent and for some time persistent, or they may soon cease. The condition is always serious, for there may be some hemorrhage into the meninges or the brain tissue, with an associated paralysis.

The relationship of infantile convulsions to epilepsy should always be noted. A considerable percentage of cases of epilepsy in children and a tangible percentage of cases of epilepsy in adults can be shown in which infantile convulsions have occurred. A careful study, therefore, of the frequency and the character of the convulsive attacks in young children may show that the child is suffering from epilepsy, and the cause of the epilepsy must be sought.

## TETANY

Although tetany was first noted and mentioned about 1830, it was almost lost sight of as an entity until about 1890, and since this date, more and more frequently, the condition has been noted and its relation to the internal secreting glands investigated.

Without discussing the history of these investigations, it will be sufficient to say that MacCallum, Voegtlin, Halsted and others have shown that the parathyroid glands are essential to health, and that their removal will cause convulsions or tetany, and later death. It was long thought that to remove the thyroid would cause these convulsions, but this effect was principally because the parathyroids were removed at the same time. MacCallum discovered that the convulsions could be stopped by feeding parathyroid glands or extract, and Halsted, by the transplantation of parathyroid gland tissue, secured the same result. MacCallum also showed that the administration of calcium salts would stop convulsive movements in animals from which the parathyroid glands had been removed. It seems established, then, that parathyroid secretion either detoxicates some product of metabolism, or that its relationship to calcium prevents the loss of calcium to the body; that calcium is a nervous sedative, or at least in its abnormal absence the nervous system is hypersensitized, so that hyperexcitability occurs and the so-called condition of "spasmophilia" develops.

While it has not yet been shown that all or perhaps even many cases of tetany can be attributed to hyposecretion in the parathyroid glands, still some necropsic findings have shown, in children who have had tetany and convulsions, that there were hemorrhages into the parathyroids, which interfered with their function. It seems quite likely that some cases of tetany and perhaps of infantile convulsions are due to disturbance in the parathyroid glands. It has been shown by some investigators that young infants suffering from spasmophilia and later proved to have some pathologic condition of the parathyroid glands, have evidenced during their period of illness a hypersensibility to the galvanic current. A clinical determination of the border-line between normal and abnormal sensibility to electric stimulation is, of course, difficult. It has long been known that sufferers from hypersecretion in the thyroid, especially as in Graves' disease, have an increased sensibility to electric stimulation.

When the parathyroids are removed and the animal is not allowed to die of intoxication calcium is not normally deposited in bone structure as has been shown in an examination of the teeth. We may, therefore, assume that parathyroid disturbance means calcium disturbance, that some instances of infantile tetany and convulsions are due to disturbed calcium metabolism, and that these convulsive movements may at times be stopped by the administration of calcium. A careful study of the food of infants in which this condition of spasmophilia is present, has shown many times that the food was poor in calcium, namely, that calcium starvation is a distinct cause of these conditions.

Dr. Clifford G. Grulee[1] of Chicago has published a suggestive article on this subject. He states that in 1905 Finklestein observed that an irritating substance prevalent in the whey of cow's milk could cause convulsions. This statement seems to have been confirmed by cases described by Grulee.[2] After he became convinced that a food consisting of a carbohydrate combined with the curds of milk the whey of which had been discarded, was relatively non-irritating in these cases, he attempted to discover by experiments on animals and careful observations on infants what the particular substance was in the whey which produced the irritating symptoms.

He based his experiments on the hypothesis that calcium and magnesium salts tend to allay nervous irritability, while sodium and potassium salts increase it; that, when there is a relative increase of calcium and magnesium over sodium and potassium salts, nervous irritability should decrease, and when sodium and potassium salts are increased relatively to calcium and magnesium, that nervous irritability should increase. Nervous irritability in infants and in animals is most accurately estimated by electric reaction, especially to the galvanic current. It was impossible, however, in his animal experiments to draw any definite conclusion as to why the tendency to tetany in infants is so markedly reduced when the whey is removed from the food.

### TREATMENT

If the little patient is in a convulsion, or convulsions occur frequently, it is of prime importance, both for the infant and for the parents, that the seizures be immediately stopped; and, of course, there is nothing more efficient and perhaps more harmless than the administration of chloroform. It takes but little chloroform to quiet the small patient, and unless chloroform must be used continuously, it probably leaves few, if any, after effects. If the convulsions recur as soon as the child comes from under the anesthetic, a hypodermic of morphin, not more than 1/30 grain for a child a year old, seems generally justifiable in convulsions (although this is a large dose) and may prevent the necessity of the frequent use of chloroform.

It is self-evident that the child must be treated symptomatically; the convulsions must be stopped, whatever the cause may be. Sometimes convulsions will cease, temporarily at least, when the child is placed in a warm bath, that is, a bath a little warmer than the temperature of the child. It should not be hot and certainly should not be cold. Cold applications to the head at the same time may be used, if deemed advisable. The object is to bring the blood to the surface of the body, to dilate the blood-vessels in the abdominal cavity, and thus to relieve the cerebral congestion and perhaps irritation. If the child has high fever, as soon as it is taken out of the warm bath an ice-cap may be applied to the head more or less intermittently, and with the precautions usual for a young infant. Persistent use of cold on the head, especially in the occipital region, is inadvisable for an infant, as its tendency is to depress the medullary centers.

Rectal injections of chloral are often used, the dose depending on the age of the child, but may be larger than should be given to the same child by the mouth; namely, from 0.20 to 0.30 gm. (3 to 5 grains) may be used.

Again, symptomatically, after the convulsions have ceased, bromids may be administered for a day or two, if there seems to be great nervous irritability or excitability. The dose should be graded according to the results; some children require a considerable amount of bromid to quiet them. A safe method is to administer 0.05 gm. (about 1 grain) every three hours, stopping if the child is drowsy.

As soon as the emergency indications have been met the physician should carefully study the condition of the child, primarily for digestive disturbance, and secondarily for all possible reflex causes. Generally, whatever the cause, a good cathartic (best castor oil) should be administered as soon as possible, or an enema may be advisable. Not infrequently there will be a history that the child has eaten something especially disturbing, and an emetic such as ipecac, or a stomach washing, may be indicated.

The child's previous diet should be carefully analyzed, looking toward the possibility of its having been deprived of nutriments that are needed for its welfare; insufficient and improper nutrition can certainly predispose to a hyperexcitability of the nervous system and to convulsions, and the indication for a radical change in diet is often evident.

Grulee reports several cases of convulsions which came under his care in which the convulsions quickly ceased after the whey had been removed from the cow's milk. Sometimes the convulsions recurred when whole milk was again given to the children. The whey-free milk treatment was supplemented in several instances by a thorough clearing out of the intestinal canal, and in other instances by the administration of chloral by the rectum. His favorite food mixture for children consists of curds of 30 ounces of whole milk with 40 ounces of arrowroot water. The amount of the curds should be diminished for younger children. Saccharin is sometimes added to the mixture, and in some cases dextrimaltose. Grulee found not only that the convulsions diminished and ceased, but also that the electrical irritability usually diminished.

That the addition of sodium and potassium salts, corresponding in quantity to those contained in the whey, did not regularly increase the electrical irritability. Grulee thinks is due to the fact that the forms in which the sodium and potassium were given, that is, sodium chlorid and potassium chlorid, either were not readily absorbed from the gastro-intestinal canal, or these salts are not in themselves the irritating factors.

---

[1] Grulee, Clifford G.: Dietetic Treatment of Convulsions and Allied Conditions Occurring in Infants, Am. Jour. Dis. Child., March, 1913, p. 205.

[2] Brulee, Clifford G.: Arch. Pediat., 1912, xxix, 24.

He sums up the results of his experiments and observations as not confirming the hypothesis that the increased electrical irritability in spasmophilia is the result of a disturbance of calcium and sodium equilibrium.

If a child shows signs of tetany, however, and certainly if it shows rickets, calcium is indicated, as well as food that contains calcium. Calcium may be given as limewater, as calcium lactate or as calcium glycerophosphate. Calcium lactate 0.05 gm. (about 1 grain) may be given three or four times in twenty-four hours; or 0.10 gm. (about 2 grains) of calcium glycerophosphate may be given in the same frequency. Calcium lactate should be dissolved, calcium glycerophosphate should be given as powder, and either may be administered in milk.

If any one of the many reflex causes of convulsions has been diagnosed, the treatment that must be instituted is self-evident.

If it is decided that the trouble is a beginning epilepsy, the treatment should be directed toward removing any possible evident cause. If no tangible cause can be discovered, bromids should be given more or less continuously to prevent, if possible, the epileptic habit. It is not the object of this article to present the exact treatment of epilepsy.

### GONORRHEA

As no method of treating this disease is the sole method approved, it behooves every physician who treats gonorrhea to study every thoughtful paper on the subject. Dr. George A. Wyeth[1] of New York has presented several recommendations for the treatment of this disease.

Wyeth thinks it is always possible to shorten, and sometimes practically to abort, acute gonorrhea. He believes that a smear of the discharge should be taken each time the physician sees the patient, and that the microscope should determine the treatment: (*a*) the microscope will show if true gonorrhea is present; (*b*) as long as gonococci are present in any number the discharge should not be checked by astringent injections, as they inhibit the local leukocytosis and phagocytosis, which constitutes Nature's method of antagonizing the gonococci and preventing their migration to other parts of the body.

Gonorrhea can be cured, Wyeth thinks, if the center of the infection be definitely located and that region scientifically treated. From his pathologic investigation of acute gonorrheal inflammations, he believes that the process is not early distributed over the entire surface of the urethra, but is predominantly lacunar and perilacunar, and also that phagocytosis is the main defense made by Nature against this germ. He finds that the gonococci on the surface of the epithelium are generally intracellular, while many in the lower strata of the mucous membrane are extracellular; when the discharge shows most of the gonococci to be intracellular the disease yields more readily to treatment and is less stubborn than when many of the gonococci are extracellular. The conclusion arrived at, therefore, is that leukocytosis and the purulent discharge should be encouraged rather than checked, as the greater number of leukocytes in the discharge the greater the likelihood that the gonococci are intracellular. Wyeth uses silver preparations in weak solutions for injection, but the method is best studied in his paper.

## New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

**DIGIPOTEN.**—Digipoten consists of the digitalis glucosides in soluble form, diluted with milk sugar to give the preparation an activity approximately equal to that of digitalis of good quality. Digipoten is standardized by the "one-hour frog" and the guinea-pig methods, and it is adjusted to an activity of approximately 1,400 heart tonic units (of Houghton). It contains from 0.3 to 0.4 per cent. of digitoxin as determined by a modified Fromme method.

*Actions and Uses.*—Digipoten has the same activity as digitalis leaf of good quality and may be used like the official drug with respect to indications and dosage.

*Dosage.*—The same as digitalis.

Manufactured by the Abbott Alkaloidal Company, Chicago, Ill. No U. S. patent or trademark.

*Digipoten Tablets.*—Each tablet contains digipoten 0.03 Gm. (½ grain).

Digipoten is prepared by extracting digitalis leaves with diluted alcohol, the alcohol being removed by distillation in vacuo, the resulting extract filtered, and the filtrate precipitated with tannin; the precipitated tannates of the glucosides are washed with water, and the glucosides are liberated in the usual manner. The resulting dark green brittle powder, which has an activity of about 12,000 to 16,000 heart tonic units, is triturated with sufficient milk sugar to reduce the activity of the finished product to the standard.

Digipoten is a pale green powder, possessing the characteristic bitter taste of digitalis. It is soluble in water and in 25 per cent. alcohol.

On ignition it leaves no appreciable amount of ash. If 0.1 Gm. of digipoten be dissolved in 2 Cc. of glacial acetic acid containing a trace of ferric chlorid and underlaid with concentrated sulphuric acid, there appears at first a brownish zone, changing to red, and finally the upper layer changes to a dark green (Digitoxin).

In addition to the biological standardization the digitoxin content of digipoten is determined by the following modified Fromme method: 30 Gm. of digipoten are placed in a flask of 500 Cc. capacity, and 270 Gm. of water and 10 Gm. of lead acetate are added and allowed to macerate for three hours with constant agitation. The precipitate is allowed to settle and 207 Gm. of the clear liquid is decanted upon a filter of a diameter of 18 Cm. The excess of lead is removed from the filtrate by the addition of 5 Gm. of sodium sulphate dissolved in 6 Gm. of water. The precipitate is allowed to settle and 164 Gm. of the clear fluid, representing 15 Gm. of digipoten, is passed through a filter. This filtrate is transferred to a separatory funnel of a capacity of 250 Cc. and 4 Cc. of ammonia water is added, after which it is extracted with four to five portions of 45 Cc. each chloroform, the successive extractions being filtered through a chloroform-wet filter into a tared Erlenmeyer flask. The chloroformic extracts are then evaporated on a water bath to a constant weight. The crude digitoxin is dissolved in 4 Gm. of chloroform and the solution is poured into a mixture of 10 Gm. of ether and 70 Gm. of petroleum ether with constant agitation. The resulting precipitate is collected on a filter of 5 Gm. diameter and washed with a small amount of petroleum ether. The washed residue is dissolved in hot absolute alcohol and rinsed into the tared Erlenmeyer flask previously used. The alcohol is evaporated on a water bath and the residue is dried to a constant weight at a temperature of 90 to 100 C. and the weight of the purified digitoxin is determined.

**TANNIGEN TABLETS.**—This dosage form of an accepted proprietary article has been accepted.

Each tablet contains tannigen 0.5 Gm. (8 grains).

## ALIMENTARY TOXEMIA—INTESTINAL AUTO-INTOXICATION

The interchangeable expressions, "alimentary toxemia" and "intestinal auto-intoxication," are employed with a degree of facility in medical literature that might lead one to suppose they designate some very definite clinical entity or easily recognizable group of symptoms. Indeed, the words have already found application in reading-matter that appeals to an even wider circle; for they enter into the advertising columns which are edited for the perusal of the layman by the exploiter of proprietary remedies.

Let us frankly admit at the outset that much, if not most, of what has been written or spoken on the subject is largely based on figments of the imagination or uncritical endeavors to provide a seemingly comprehensive general explanation for a variety of unrelated common symptoms of human malaise. In the midst of all this ignorant and pseudoscientific argument it is refreshing to hear of the review of the real status of the question of alimentary toxemia and of the frank exposure of the limitations and inconsistencies of current knowledge of a hazy topic which was made by some of the speakers in a recent symposium on this theme before the Royal Society of Medicine in London.[1] Dr. W. Hale White, in particular, called attention to the fact that much that is maintained in reference to alimentary toxemia really is inadequate and unjustified. Presumably what is usually meant by this term is an illness due to poisons absorbed somewhere in the alimentary canal and produced within the gastro-intestinal tract by microorganisms resident therein. Yet no one who accepts this point of view can explain what these poisons really are nor can he identify the bacterial organisms which are charged with pernicious chemical activity. As Hale White notes, the expression "alimentary toxemia" at once shows our ignorance, for it is unscientific to group cases of poisoning according to the point at which the poison entered the body. The nature of the poison should be the distinguishing factor; "it is a minor matter whether our murderer comes in at the window or at the door."

While protesting against the current practice of talking learnedly where ignorance still reigns supreme, we need not despair of decided progress in the future. Hitherto it has been indol and its derivatives, phenols, a few diamins like putrescin and cadaverin, hydrogen sulphid, and a few other compounds—but particularly the first group—which have had to bear the burden of the charge of specific toxicity in the discussions on auto-intoxication. Research in the field of biochemistry is, however, continually adding new possibilities in this direction. The production of highly active substances like beta-imidazolethylamin from histidin in the alimentary tract is an illustration. There are, without doubt, numerous other pharmacologically potent compounds derived from our food-fragments by bacterial reactions which proceed beyond the limitations of the reaction of the ordinary digestive enzymes.

It is by no means unlikely that what is termed alimentary toxemia may in some cases really be hepatic disease—that the failure of the liver to protect the organism is the real fault. Dr. Saundby insists that under physiologic conditions the natural protective agencies in the alimentary system are sufficient to shield the body from the dangers of poisons formed therein or those introduced with the food, provided that these are not overwhelming in amount. Such morbid symptoms as arise may well result from a breakdown in the protective machinery in consequence of functional defects or pathologic changes in the organs concerned. When we ask, however, what the latter may be, no reply that extends beyond the suggestion of analogies is forthcoming.

Of course, no discussion of alimentary auto-intoxication is complete without reference to intestinal stasis as a predisposing cause. What symptoms and conditions have not been ascribed to this? Cystic disease of the breast, cancer, duodenal ulcer, Bright's disease, exophthalmic goiter are actual examples. As a matter of fact infrequent evacuation of the bowel is consistent with perfectly good health and longevity; and simple constipation—that is, mere fecal retention—by no means necessarily favors the production of poisonous substances or the occurrence of pathologic symptoms. If, however, alterations in the wall of the alimentary tract have taken place many symptoms may result from fecal stasis; and it is perhaps to such inflammatory consequences that objectionable accompaniments of constipation may be attributed. We are favorably impressed by the remark of Saundby that so long as the several organs concerned are structurally healthy, the intestinal contents are practically outside the body and are powerless to injure us. Infrequent or incomplete evacuation of the colon is not of itself necessarily a cause of disease.

If the ill health involved in the conditions under discussion were due to special bacteria the best treatment would be to prevent the ingestion of the offenders. Owing to our ignorance of the cause this cannot be done. Nor does the use of so-called intestinal antiseptics offer any promise of success. The widely proclaimed sour-milk therapy has sought to prevent the formation of the medium in which the bacteria grow; but the outcome is frankly uncertain if not actually disappointing. Where there is delay in emptying the bowel, a dozen and one devices, from the simplest aperient to the most complex hydropathic treatment, are available, and some surgeons like Arbuthnot Lane have been trying to limit the hypothetic formation of hypothetic poisons in the intestine by preventing delay of evacuation through the short-circuiting or removal of the large bowel. Here we cannot refrain from quoting the words of Hale White: "When these cases are reported we are always assured that all medical means had been adopted without benefit, but we are never told what the medical means were. . . . A suspicion comes to one's mind sometimes that perhaps some surgeons do not know all the means the physician has at his command for the treatment of delayed action of the bowels."

## MAN, MONKEY AND THEIR PARASITES

The so-called specific immunity reactions which have been so extensively investigated in recent years have emphasized some unusual relationships among animal species. These have expressed themselves, for example, in the precipitin and hemolysin reactions. The serum of an animal immunized against human blood gives also a precipitate in the serum of the anthropoid apes. Similarly the hemolysins specifically developed to lake human blood-corpuscles act on those of the man-like apes. The reaction at once ceases, however, in the case of the ordinary monkeys.

A recent writer remarks that embryology, paleontology and comparative anatomy may have taught the same general facts, but it comes as somewhat of a shock to many to realize that man's kinship to the monkey goes so far as a "blood relationship." Few persons are as yet aware of the fact that this relationship of man by no means applies to all of the monkey tribe, but only to that group including such examples as the chimpanzee, orang, gorilla and gibbon, and not to the more common monkeys of the *Macacus* type. This subtle distinction shown in the various serum reactions is of unusual scientific interest. V. L. Kellogg, entomologist of Leland Stanford Junior University, has furnished a new and somewhat startling kind of evidence of the relationship of man to the anthropoid group of apes in distinction from others of the monkey tribe. It is based on the contention that the host distribution of the wingless, permanent skin parasites (ectoparasites) of the higher animals, including birds and mammals, is governed more by the genetic relationships of the hosts than by geographic range or any other environmental condition.[1] If this is correct the kinds of permanent ectoparasites found on individuals will indicate in some measure the genetic relationships of the hosts.

According to Kellogg[2] the wingless, permanent ectoparasites of birds and mammals are of two groups, namely, the biting lice, *Mallophaga,* feeding on the feathers and hair, and the sucking lice, *Anoplura,* feeding on blood. Certain mites (*Acarina*) may perhaps also be assigned to this category of permanent wingless parasites, but the fleas cannot be, for they hop on and off their host, and all their immature life is non-parasitic and wholly apart from their future hosts. The *Mallophaga,* of which nearly two thousand species are now known, occur chiefly on birds, while the *Anoplura,* of which less than a hundred are known so far, are confined to mammals. No biting lice have been found on man or on any anthropoid.

Sucking lice of species representing two genera, *Pediculus* and *Phthirius,* occur on man. Representatives likewise have been found on the anthropoid gibbons and chimpanzee. The other tailed monkeys which, in contrast with the man-like apes, are shown by the "blood relationship" tests to be unrelated to man, harbor parasites of entirely distinct genera. The resemblance of man to his simian cousins crops out in this most unexpected fashion.

How these remarkable affinities of host and parasite are preserved is not easy to explain. The California entomologist responsible for the facts recited states that he has often become, in the course of collection, the temporary host of various bird- and mammal-infesting biting lice, but these parasites all seemed as anxious to escape as he was to have them. And they did escape; or, if they did not, they died in a few hours. There is, indeed, an extraordinarily exact fitting of parasite to host in the case of biting and sucking lice. It is hard to understand—to quote Kellogg—of just what details this fitting consists, beyond the more obvious structural and morphologic differentiations. The essential fitting is far more subtle. It is a fitting to the host's physiology as well as to its epidermal structures.

## THE STATUS OF THE BOUILLON CUBE

A survey of the advertising literature in which catch-phrase display-lines form a conspicuous feature reveals the novel expression "bouillon cubes" among the more recent innovations. We assume that the thinking part of the purchasing public, and above all the physicians, have by this time been educated into an appreciation of the limitations of extract of meat as a source of nutriment to the human body. There was a day when, owing to the domination of Liebig's teachings and the influence of his honored name, beef extract was looked on as embodying the very essence of nutrition. The fact that the nitrogenous extractives of muscle tissue furnish to the organism neither constructive material nor energy in any noteworthy amount does not, of course, impugn their efficiency in vigorously exciting the secre-

tion of the gastric juice, promoting the flavor of foods into which the extract of meat may enter and in rousing the appetite. We must never lose sight of the fact that this is their true function in both health and disease. They are flavoring agents and, in the words of a well-known writer on dietetics, "their proper place is in the kitchen and not by the bedside."

However widely this fact may deserve appreciation and even seem to receive it at present, the American public is a gullible one. From the claim that extract of meat — to quote some actual representations of misbranding — is "a concentrated food that represents the nourishing constituents of fresh beef," or "a combination of all the strengthening and stimulating properties of prime lean beef," or "the most perfect form of concentrated food known," it has been a short step to another suggestive type of advertising. Now it is to the category of the "brain-fag" relievers that the extract of meat in its up-to-date guise of bouillon cubes has been consigned by the present-day exploiter. Undue claims of nutritive superiority are no longer made; but the meat extractives have joined the brigade of ready-relief specifics which are intended to enable the jaded worker to finish his day's task. At any rate the rôle of the bouillon as stimulant alone is implicitly recognized in this latest enterprise.

Without entering here into the physiologic or dietetic merits of the propaganda for beef-tea drinking, we may nevertheless call attention to some economic fallacies involved in the use of bouillon cubes and point out some unexpected features of their composition.[1] Common salt is the foremost constituent, contributing from 49 to 72 per cent. of the total weight of the cubes of ten leading brands manufactured in the United States and Germany last year. The amount of real meat extract present ranged from 8 per cent. in the poorest to only 28 per cent. in the best brands marketed. It is true, to speak in all fairness, that most of these cubes have *no* advertised claim to be concentrated beef broth or essence. Many persons, however, believe them to be so. little realizing that cubes which contain about two-thirds salt and never more than one-third meat extract are an expensive form of securing the flavor and other virtues of the latter.

Home-made meat broth or meat and vegetable soups contain more meat extractives and real nutrients than the commercial preparations, and they are cheaper than the bouillon or soups prepared from commercial cubes, extracts or juices.[1] This fact need not, however, condemn the popularity of a harmless ready-to-use expedient in the hasty and convenient preparation of a cup of palatable bouillon. One might as well argue that the nutritious ready-to-eat cereals are to be rejected because they are more expensive and, in the taste of many, more palatable than the old-fashioned oatmeal which requires a somewhat laborious culinary treatment. Our contention is that the public, and the physician in particular, should be educated to know precisely what is involved when claims pertaining to diet as well as to drugs are made to attract a purchaser. They can then intelligently count the cost, and balance convenience and elegance against personal effort and economy.

---

[1] Those who are specially interested in this topic will find additional details in a publication by *Cook, F. C.*: Bouillon Cubes: Their Contents and Food Value Compared with Meat Extracts and Home-Made Preparations of Meat. Bull. 27, U S. Dept. Agric., Washington, 1913, p. 7.

## WHERE IS SUGAR BURNED IN THE BODY?

There can be little doubt that the chief seat of the destruction of sugar, the form in which the carbohydrates are finally utilized in the body, is located in the musculature. Energy is immediately needed there and there it is doubtless liberated in the course of the metabolism of the carbohydrates. Older experiments of Chauveau and Kaufmann have indicated that the venous blood flowing from a contracting muscle contains less sugar than the arterial blood flowing to it. A similar consumption of glucose, the normal blood-sugar, has been described as occurring in the isolated contracting mammalian heart when fed with Ringer's fluid containing a small proportion of the carbohydrate in question. We have on a previous occasion pointed to the observations of Knowlton and Starling[1] that a heart, fed with blood and performing a normal amount of work, is able to use up sugar, the consumption of the latter amounting to about 4 mg. per gram of muscle per hour.

The foregoing considerations, though plainly involving the muscle in the metabolism of the carbohydrates, do not elucidate the precise conditions under which the sugar utilization really takes place. Some years ago Professor Cohnheim[2] of Heidelberg offered evidence which he believed demonstrated that the muscles contain an enzyme which can facilitate the combustion of sugar. According to Cohnheim it was not present in the muscle in a preformed state, but required an activator which was furnished by the pancreas. Experiments *in vitro* with muscle tissue-juice and sugar, with and without additions of pancreatic extracts, seemed to substantiate this thesis. It was an interesting outlook, since the alleged facts afforded a convenient basis for attractive hypotheses regarding the undeniable rôle of the pancreas in carbohydrate metabolism, in conjunction with the necessary postulates respecting the participation of the muscles.

The subsequent history of this episode, with its contentions that Cohnheim's results were due to contaminations of a bacterial nature, the repetitions by other workers, the successive contradictory announcements of results now positive, now negative, form a spirited chapter in the investigation of tissue function. The complete exclusion of bacteria in experiments on isolated tissues calls for the greatest care and refinement of laboratory tech-

nic. A recent reviewer, Professor von Fürth of Vienna,[3] while admitting the justification of much of the criticism in this field and inclining to an attitude of skepticism toward the repeatedly reported demonstration of sugar destruction by isolated muscle substance, cannot become convinced that, after all, there is not some active factor involved. We are thus prepared for the latest venture in this field of research. Gigon and Massini[4] at Basel have taken up the problem anew. Again we have the story of extreme precaution in the conduct of the tests, the supreme importance of such precaution having been prominently emphasized through much well-directed criticism in the past. The outcome was positive. Sugar was found to disappear when digested aseptically with fresh comminuted muscle tissue. The loss of sugar was not merely small but pronounced.

Reports of this sort, encouraging the belief that the destruction of sugar under the influence of some thermolabile component of muscle tissue is at length definitely demonstrated, are renewed from time to time apparently regardless of the undisputed fundamental findings of Levene and Meyer[5] which bring the subject into a new light. According to these investigators at the Rockefeller Institute in New York the disappearance of glucose noted in even the most carefully conducted experiments with the various tissue extracts is not due to destruction, oxidation, or "combustion" of the sugar, but merely to its synthesis or condensation to compounds of larger molecular weight which do not respond so readily to the analytic methods commonly employed. These important researches place the alleged use of sugar by the tissues in such experimental trials on an entirely different basis. They cannot be overlooked even though they run counter to the hopes which have so often been raised of a final answer to the question which heads these remarks.

---

## DO THE KIDNEYS HAVE SECRETORY NERVES?

The wonderful adaptability of the kidneys to certain needs of the organism, and the ready response which they show to seemingly minute changes in the chemical environment of their cells and to more remote circumstances that determine the conservation or elimination of water under sundry conditions, inevitably suggest an inquiry into the nature of the renal mechanism. It has been a familiar experience to rely on the nervous system to explain the more subtle regulatory functions of the organism. In the glandular organs, in particular, the rôle of secretory nerves has long been a prominent one. The dependence of the alimentary digestive secretions on the participation of nervous stimuli in many of the secretory manifestations affords a classic illustration of this familiar relationship. The kidneys have been among the last of the glandular organs to resist the attempt to explain their secretory behavior by the assumption of nervous factors. Gland structures like the adrenals, in which the conditions for the demonstration of the direct participation of nerve stimulation are far from ideal, because the measurement of the effect of the conjectured nervous impulses must be a very indirect one, have nevertheless of late given evidence of secretory innervation in the hands of such investigators as Asher, Elliott and Cannon. The thyroids have been under suspicion in respect to a possible nervous control and have not lacked the charge, as yet not satisfactorily sustained, of response to secretory nerves.[1] It has been generally admitted or assumed, however, that the activity of the kidney must be determined primarily by chemical stimuli. The delicate sensibility which it displays in reacting to the slightest deviation from the normal of blood composition, by excreting water or dissolved substances, is thus analogous to the form of humoral regulation on which the efficiency of the "hormones" is supposed to rest.

The local nervous mechanism of the kidneys has been believed to affect their secretory activity in the direction of augmenting or decreasing it solely by corresponding alterations in blood-supply. The widely—and we believe almost universally—accepted belief that the vasomotor mechanism and changes in the vascular supply furnish practically the only way in which the central nervous system can directly affect the secretion of the kidneys has lately been questioned by Asher and Pearce.[2] Through direct experiment by the familiar methods of nerve stimulation they have reached the conclusion that the vagus contains secretory fibers for the kidney, and that the stimulation of these fibers initiates an increased secretion of urine. The elimination not only of water, but likewise of other urinary components is promoted by the intermediation of these vagus nerve impulses. The investigators seek to fortify their contentions by pointing out that the necessary correlated anatomic evidence is not wanting; for Smirnow[3] is said to have demonstrated nerve-endings in the epithelial cells of the urinary tubules.

It is obvious that if the conclusions of Asher and Pearce are substantiated a revision of many existing ideas in reference to renal secretion may be called for. Purely mechanical explanations of diuresis and the action of drugs on the kidneys must be examined in the light of the new evidence.

We may safely assume that a statement of such far-reaching importance advanced by workers well known in the field of physiologic research will receive prompt critical examination, the results of which must be accepted by those who are interested in the theory of glandular functions.

## HAS THE VIRUS OF VACCINIA AND VARIOLA BEEN OBTAINED IN PURE CULTURE?

The virus of variola and of vaccinia is less sensitive to the action of glycerin than bacteria in general, and for this reason it is possible to obtain an almost pure virus of practically full strength. Prolonged action of the glycerin, however, destroys the virus, but more rapidly at 37 C. (98.6 F.) than in the cold; if kept at from — 5 to — 15 C. (from 23 to 5 F.), glycerinated virus may remain active for years. A consideration of these facts led Fornet[1] to try other sterilizing agents, which, while freeing the virus from bacteria, would permit of its being preserved by other means than freezing. Ether was found to be such an agent, etherized virus remaining sterile and active for weeks after inoculation on various culture-mediums, such as broth, agar, etc. The continued activity of the virus thus treated was tested by inoculation of rabbits, calves and human beings with the usual typical reactions of vaccination. Etherized virus has even been carried through a series of inoculations on broth, beef-serum and agar without apparent loss of virulence, and Fornet concludes that there is hardly any doubt that proliferation must have taken place. He calculates that in the last instance the dilution of the sterilized virus would have reached 1 : 1,000 billions if there had been no growth; hence, if Fornet is right, growth without doubt did occur. Examined with the ultramicroscope and in other ways, the supposedly pure cultures of virus show minute structures that appear somewhat as diplococci of unequal size surrounded by a clear zone. Similar bodies were found in "cultures" prepared in the same way with the contents of a small-pox pustule. If these results can be repeated, a great advance will have been made, as there will be opportunity not only to study the virus in pure culture, but also to provide a better virus than now available for vaccination. The principle involved may be applicable to other diseases and will soon be given a thorough trial.

## ARSENICAL MYELITIS FROM NEOSALVARSAN

Following the introduction of salvarsan as a therapeutic agent came occasional reports of arsenical poisoning in cases in which it was administered. Many of these were explained as due to overdosage, or to fault in the technic of administration, but ill results occurred which admitted of no such explanation. Gradually neosalvarsan, a compound of arsenic of somewhat more complex molecular structure than salvarsan, has come into use, and experience indicates that it is the safer agent of the two; but neosalvarsan is not without its dangers. Thus Chiari[2] reports a case of myelitis ending in death which in all likelihood was caused by neosalvarsan. The patient was a woman, aged 27, with secondary syphilitic manifestations; she received three intravenous injections of neosalvarsan at four-day intervals, in all 3.3 gm. Immediately after the last injection a scarlet rash appeared, followed by severe vomiting and a few days later by inability to void urine. Six days after the last injection sensory and motor disturbances appeared, progressing to a definite inferior paraplegia. Large, rapidly spreading bed-sores developed, and also a severe cystitis. The condition progressed steadily with severe pains in the legs, diarrhea and anemia, to a fatal termination in six months. Necropsy showed extensive degeneration in the anterior horns and anterior and lateral columns of the cord. In the seventh to ninth dorsal segments the process was so wide-spread that no normal nerve-tissue was discernible in a cross-section of the cord. There was nothing in the clinical history or post-mortem findings which suggested any other explanation of the development of this condition than arsenical poisoning. Chiari cites similar cases and calls attention to the parallelism between the symptoms in these cases and those sometimes manifested in arsenical poisoning from other sources. In salvarsan and neosalvarsan reliance is placed in combinations of arsenic of complex molecular structure. In this form the arsenic is relatively non-toxic, but as in the case of many other compounds, the biochemical agencies of the body may split the complex chemical structures into simpler ones, reducing the non-toxic combinations into products which may be highly toxic to the tissues of the human organism. So long as we are not able to predict with certainty what chemical reactions may take place within the body under various conditions, there will remain more or less risk connected with the administration of drugs so potentially toxic as are these higher compounds of arsenic. For future guidance, all instances of unfavorable outcome after their use should be recorded in detail with great care.

## OVERCROWDED STREET-CARS

A narrow car; seats filled with persons attempting to read newspapers while the car swings and jolts along its way; aisles jammed with men and women, boys and girls and tiny children, swaying and rubbing, one against the other, coughing and sneezing, pushing and pressing — what a sight for a progressive age; what a sermon for the moralist; what a despair for the student of public health and hygiene! Endless problems are presented by this picture, seen daily in nearly every American city. Most important is the menace to health from the thousands of bacteria, hidden in the throats of diseased men and women, and sprayed directly into a stagnant air, moist and unmoving in the absence of sufficient means of ventilation. Virulent organisms are inhaled into the throats and lungs of tired workers and tiny babes, who form an excellent host for their quick cultivation. The fare for the ride is small, but the cost cannot be estimated in terms of dollars and cents.

## DANCING FOR THE AGED

The following newspaper item just received emphasizes the point made in our comment last week regarding the danger for old persons of the newer dances:

> Shortly before midnight last night at his home, occurred the death of Dr. ———, who for more than forty years had practiced his profession in this city. His death is all the

---

# Medical News

## CALIFORNIA

**New Hospital Assured for University.**—The task has now been completed of raising $600,000 in subscriptions for the erection of a new teaching hospital for the University of California. The work of securing the subscriptions was in the hands of Regent William H. Crocker, Dean Herbert C. Moffitt of the Medical Department of the University of California, and Dr. Wallace I. Terry. Plans are now being prepared by Mr. Louis Hobart for this new University Hospital, which will be started next spring on the "Affiliated Colleges" site on Parnassus Avenue, San Francisco, adjoining the present University of California Hospital. Among the principal donors were John Keith of San Francisco, who gave $150,000 in memory of his wife; Mr. William H. Crocker and Mrs. Harriet Alexander, who gave $50,000 each; and Mr. Charles Templeton Crocker and Mrs. Malcolm Whitman, who gave $25,000 each, this $150,000 being in memory of the late George Crocker, who founded the Cancer Research Fund entrusted to Columbia University.

## ILLINOIS

**Personal.**—Dr. George A. Zeller, superintendent of the Peoria State Hospital, has been appointed alienist of the state board of administration, vice Dr. Frank P. Norbury, Springfield, resigned.——Dr. Harry M. Hayes, Peoria, who has been seriously ill at the Proctor Hospital with typhoid fever, is reported to be improving.——Dr. Rockwood Sager, Rockford, is reported to be critically ill at his home.

**Health Conditions in Chicago.**—The *Bulletin of the Chicago Department of Health*, November 8, reports that the death-rate in the city of Chicago for the ten months of 1913 from all causes was 15.3 per 1,000 as against 13.8 for the same period of 1912. The report states that in nearly all diseases that contribute most heavily to the death-rate increases are shown over the corresponding period of 1912, particularly with reference to the dirty air diseases, influenza, pneumonia and tuberculosis. Scarlet fever showed the largest increase, with a record of 852 deaths for 1913 as against 452 for the same period in 1912, an increase of 400 deaths. During this period in 1913, increases are shown in the number of deaths from measles and diphtheria and the diarrheal diseases of children under 2 years of age. The month of October, however, showed an improvement over the corresponding month of the previous year, except that the typhoid deaths amounted to forty-two as against twenty-two for October, 1912. The narrow source from which a large number of typhoid cases frequently come is illustrated in the typhoid in Chicago. Ten cases were traced to one milk-wagon driver who stayed at work after he fell sick. Twenty-nine cases were traced to one kitchen helper who came to Chicago from St. Louis half recovered from typhoid. To Oct. 1, 1913, thirty-nine out of each 100 cases of typhoid in Chicago had contracted the disease outside of the city.

### Chicago

**Dispensary Opened.**—The Salvation Army has opened a free dispensary at 6 East Seventh Street, where Dr. George Ensminger will be in attendance from 12:30 to 2:30 p. m. daily.

**Examination for County Hospital Positions.**—Thirty-four physicians on the staff of the Cook County Hospital took the examination for chiefs of the thirteen departments, November 28.

**Isolation Hospital Site.**—The finance committee of the city council voted November 25 to purchase about 18 acres of land, lying south of the bridewell, for $185,000. The site is to be used for a new isolation hospital and for other municipal buildings.

**Small-pox in the Healthatorium.**—Once on a time there was a group of men whom Nature had endowed with many muscles and a peculiar conformation of cranium. Having much muscle and a modicum of medical knowledge they founded a school of "physcultopathy" which is a hybrid of uncertain etymology, the significant part being "cult," which has been described by the Chicago Health Bulletin as "a group of individuals who frequently claim as one of their cherished privileges the right to disseminate false information concerning the efficacy of vaccination against small-pox." Now there came to the home of the cult, which was known as the Macfadden Healthatorium, a humble unvaccinated disciple from Idaho. Ten days after he arrived, he came down with small-pox, which was unrecognized as such, having no legal existence under the laws of a Healthatorium. He returned to the school while in a contagious state and now ten other unvaccinated disciples are guests of the isolation hospital. A newspaper clipping continues as follows:

> "Dr. Spalding said he held the authorities at the Macfadden school in no wise culpable, but he said none of the patients had been vaccinated.
>
> "At the physical culture school last night students, patients of the sanitarium and employees were nursing arms vaccinated by the health authorities. About seventy-five were vaccinated.
>
> "In the homes of the six patients like precautions were taken. Members of their families were all required to undergo vaccination.
>
> "The healthatorium was in charge of Charles D. King. He showed no alarm over the outbreak.
>
> "A. M. Wood, the manager of the healthatorium, said he felt no cause for alarm."

One of the patients has said that if King and Wood had small-pox, he would feel no alarm. The general conclusion reached is that although a mass of muscle will move mountains, a good vaccination is more powerful in preventing small-pox.

## INDIANA

**Hospital Funds Secured.**—The campaign opened by 200 men of Marion and Grant County, October 14, to raise $40,000 for a new hospital for Grant County, was closed after eight days with a total subscription of $45,005.90.

**New Officers.**—Twelfth District Medical Society in Fort Wayne, November 5: president, Dr. James W. McKinney Bluffton (reelected); councilor, Dr. Elmer E. Morgan, Fort Wayne.——Eleventh District Medical Society at Peru, October 16: president, Dr. George R. Daniels, Marion; secretary-treasurer, Dr. James L. Gilbert, Logansport (reelected).

**New Hospitals.**—St. Joseph's Hospital, Ft. Wayne, which has been erected at a cost of $150,000, has just been completed. The building is six stories in height and is in charge of the Poor Handmaids of Jesus Christ.——The corner-stone of the North Pavilion of the Methodist Hospital of Indianapolis was laid by Bishop William F. Anderson, November 26.

**Conference of Charities.**—The twenty-second annual session of the Indiana Conference of Charities and Corrections was held in Gary, November 17 and 18, and the following physicians were elected to office: vice-presidents, Dr. Kipplinger, Michigan City, and George R. Green, Muncie, and chairman of medical committee, Dr. Charles P. Emerson, Indianapolis.

**Personal.**—Dr. Walter R. Cleveland has been appointed president of the Evansville Board of Health.——Dr. Martin K. Kreider, Goshen, has been appointed a member of the board of trustees of Clarke Hospital, Elkhart.——Dr. James A. Taylor, Montpelier, has been elected secretary of the newly organized Blackford County Association for the Study and Prevention of Tuberculosis.

**Secretaries of Tuberculosis Society Organize.**—The organization was perfected in Indiana, October 17, by secretaries of city and county tuberculosis societies. W. D. Thurber of Indianapolis was elected president and C. A. Hartsley, Evansville, vice-president; Mrs. E. B. Connolly Kehrer, Anderson, secretary-treasurer, and Dr. A. L. Ziliak, Princeton, chairman of the executive committee.

## IOWA

**New Officers.**—Southwestern Iowa Medical Association at Burlington, November 20: president, Dr. Coral R. Armentrout, Keokuk; secretary-treasurer, Dr. Edward F. La Force, Burlington. Mount Pleasant was selected as the next place of meeting.

**Personal.**—Dr. J. B. Gardner, Manilla, is critically ill in the Methodist Hospital, Omaha.——Dr. C. De Witt Rawson, Otley, was seriously injured by the overturning of his automobile, November 13, near Otley.——Dr. W. E. Sanders has been appointed head of the pathologic department of the Methodist Hospital, Des Moines, and Drs. John H. Peck, J. Z. Strawn, Milton G. Sloan, Matthew L. Turner and Nellie S. Noble have been added to the medical staff of the institution.——Dr. Ray R. Kulp, Davenport, fractured his right arm while cranking his automobile, November 10.——Dr. Harry R. Layton, Leon, who has been critically ill, is reported to be improving.

## MARYLAND

**Musicale Given by Physicians.**—A musicale was given at Osler Hall, Baltimore, November 11, by the Doctors' Orchestra and the chorus of the Medical and Chirurgical Faculty of Maryland, for the benefit of the Book and Journal Club. Dr. John Wade directed the orchestra and Dr. B. Merrill Hopkins conducted the chorus.

**Personal.**—Dr. and Mrs. Curtis F. Burnam, Baltimore, sailed for Europe November 19.——Lieut. John C. Stansbury, M. C., N. G. Md., has been commissioned captain and placed in command of Field Hospital, No. 1, succeeding Major Howard E. Ashbury, made a member of the general staff.——Lieutenants G. Milton Linthicum and Frederick H. Vinup, Baltimore, have been promoted to captaincies and assigned to duty with the Fifth and Fourth Infantry, respectively.

**Academy of Science Meets.**—The National Academy of Science, after a two days' session at Johns Hopkins University, closed its meeting with a dinner at the Maryland Club at which Dr. Welch presided as toastmaster. Dr. Simon Flexner, New York City, discussed the causes of infantile paralysis, the experiments made in isolating the germs of the disease and the effects of the virus on monkeys. Dr. Howard A. Kelly made an address on "Radium as a Cure for Cancer."

**New Officers.**—Medical Association of Harford County at Havre de Grace: president, Dr. J. Lee Hopkins, Havre de Grace; secretary, Dr. Charles Bagley, Bagley.——Medical Society of the University of Maryland at Baltimore, November 19: president, Dr. Albert H. Carroll; secretary, Dr. Edward J. Maldeis.——Washington County Medical Society at Hagerstown, November 13: president, Dr. Daniel A. Watkins; secretary, Dr. Ivan M. Wertz, both of Hagerstown.——Frederick County Medical Society at Frederick, November 12: president, Dr. Ralph R. Browning, Myersville; secretary, Dr. Bernard O. Thomas, Frederick.

**Academic Day Exercises.**—At the academic day exercises at the University of Maryland and St. Johns College, November 11, the honorary degree of LL.D. was conferred on Geheimrat Privy Councilor, Prof. Adolph Schmidt, of the medical faculty of the University of Halle. Dr. Schmidt was presented by Dr. John C. Hemmeter, who spoke briefly of the achievements of the German professor. The memorial address for Dr. Eugene F. Cordell, eminent as a medical historian and a member of the faculty of the university, was delivered by Dr. Ralph Winslow. After the academy day exercises luncheon was served at the Emerson and the annual alumni dinner was held in the evening.

## MASSACHUSETTS

**Addition to Hospital.**—The Board of Health of Springfield is building an addition to the Municipal Tuberculosis Hospital to be used by nurses. The addition is 21 by 16 feet and one story in height.

**State Board Appointment.**—Dr. George L. Richards, Fall River, has been nominated by Governor Foss as a member of the state board of registration and medicine to succeed the late Dr. Edwin B. Harvey, Boston.

**State Board Approves Recommendations.**—The Industrial Accident Board of Massachusetts has notified the Essex North District Medical Society, that it has approved the following recommendations of the medical advisory committee and will apply them as far and as soon as practicable.

1. That a permanent Advisory Medical Committee is necessary.
2. That we consider it inexpedient to have a medical man as a member of the Industrial Accident Board.
3. That the Industrial Accident Board should have a consulting surgeon on whom should fall the duty of detail work in preparation of matters to be laid before the Advisory Committee. Matters in dispute regarding services and fees of physicians should be referred to this Committee for recommendation.
4. That insurance companies be requested to provide suitable blanks for notifications as well as specifications of services rendered by physicians.
5. That Industrial Insurance Companies be encouraged to allow all reputable physicians to render services in industrial accidents provided they are willing to render such services on reasonable basis.
6. That the Accident Board should make arrangements with which the insurance companies should cooperate, that any physician whose bill is in dispute may appear before a representative of the Accident Board within a reasonable distance of his home.
7. That the Accident Board shall provide for medical referees by districts.
8. That fees paid by the companies should not be less than the average minimum fee in the locality in which the service is rendered.
9. That charges up to $50 for major operations are not excessive.
10. That physicians appearing at hearings before the Board shall receive the compensation as provided for under Section 8, Part 3,
11. That services rendered by lodge physicians be paid for, provided it is not inconsistent with the rules of the order.
12. That specialists, established and recognized by the profession as such, may receive special rates for their work, provided the case requires special skill.
13. That the ruling previously made by the Accident Board, that "fees should not be charged an injured party whose employer was insured larger than the injured party would be charged were he not insured," should be interpreted to mean that in a given accident the fee paid by the insurance companies for services should not be less than the average minimum fee for similar services in the locality in which said services are rendered.

## MISSOURI

**St. Louis Leper Escapes Quarantine.**—Charles Hartman, declared a leper by the St. Louis Board of Health, has left the leper quarters of the Robert Koch Quarantine Hospital and is believed to be on his way to Mexico.

**Exposure of Quacks.**—At a meeting of the St. Joseph-Buchanan-Andrew County Medical Society at St. Joseph, October 15, a committee, consisting of Drs. O. G. Gleaves, Pierre I. Leonard and Luther A. Todd, was appointed to make [illegible] investigation as is necessary to the exposure of quack [illegible] uthority to employ an attorney.

**Hospital News.**—The new Deaconess Home and Hospital to be erected by the Methodist Episcopal Church in St. Joseph will be five stories in height, and will accommodate five times as many patients as the Ensworth Hospital.——The Sedalia General Hospital was damaged by fire November 11. Five patients were removed from the building and the loss is estimated at $2,000.

**Personal.**—Dr. John G. Hayden, Kansas City, was operated on recently in Chicago for appendicitis.——The barns of Dr. J. H. Roney and Dr. W. G. Estill, Lawson, were burned, November 10.——Dr. David R. Porter, Kansas City, was the guest of honor at a dinner given by fifty of his friends and pupils to celebrate his seventy-fifth birthday anniversary. Dr. J. F. Binnie served as toastmaster.——Dr. Frank C. Wallace, formerly assistant physician at City Hospital No. 2, St. Joseph, has been appointed city physician of Maryville.——The suit of Dr. H. H. Temple, Kansas City, against the Union Pacific Railway and the Pullman Company, in which $40,000 damages was claimed, has been compromised for $3,500.——Dr. Arthur H. Kelley, Rosendale, was stabbed November 14, and is said to be in a serious condition at the Ensworth Hospital, St. Joseph.——Dr. Amos T. Fisher, Maryville, has been appointed assistant physician at State Hospital, No. 2, St. Joseph.——Dr. Amos A. Freymann, Kansas City, was seriously injured in a collision between motor-cars, November 10.——Dr. George E. Krapf, superintendent of the German Hospital, has resigned and has been succeeded by Dr. C. Emil Simon.——Dr. Charles W. Schery has been appointed assistant city bacteriologist.

## NEW YORK

**New Officers.**—Medical Society of the County of New York, one hundred and eighth annual meeting, November 24: president, Dr. T. Passmore Berens; secretary, Dr. John Van Doren Young, both of New York City.

**Open-Air School Nearly Ready.**—The new open-air school for Rochester at Cobb's Hill will be ready for occupancy about December 15. The school will accommodate about one hundred pupils, and will have cost about $10,000 when completed and equipped.

**Tuberculosis Pavilion Opened.**—The east wing of the Children's Tuberculosis Pavilion, Buffalo, has been temporarily fitted up with stoves, electric lights and the necessary plumbing. The building when completed will have cost about $17,000 and will accommodate about forty patients.

**Personal.**—The health officers of New York State at their thirteenth annual conference, November 20, unanimously indorsed the nomination of Dr. Eugene H. Porter as state health commissioner.——Dr. Daniel W. Nead, medical examiner for the Pennsylvania System, at Buffalo, has been transferred to a similar position at Reading, Pa.——Dr. W. Charles Willis, Central Islip, L. I., has sailed for Europe.——Drs. Ward E. Hunt and J. G. McGillicuddy, Little Falls, have been appointed coroners.

**To Make Saratoga Springs a Spa.**—The commissioners of the state reservation have sent a letter to all physicians belonging to county medical societies describing the possibilities of Saratoga Springs as a spa and telling of their plans for the development of the State Geyser Park of over 250 acres. An advisory council is being formed to study the conditions at the springs, and suggest methods for the development, and advise with the commission. It is requested that each county medical society elect immediately a corresponding member of the council, who shall receive the reports and bulletins issued by the commission and shall communicate to his society the facts concerning the progress of the work and shall present annually a brief paper on the springs and their uses, and that it communicate the name and address of the corresponding member at once to Dr. Albert Warren Ferris. It is also requested that each county society arrange for a special or regular meeting, to be held in December, at which a brief paper on the springs shall be presented by the corresponding member of the council.

## New York City

**Harvey Society Lecture.**—The next lecture will be given December 13. The speaker will be Dr. Rufus Cole of the Rockefeller Institute for Medical Research, who will speak on "Pneumococcus Infection and Lobar Pneumonia."

**German Physicians Elect.**—The following officers have been elected by the German Medical Society: president, Dr. Gustav Seeligmann; vice-president, Dr. H. Fischer; recording secretary, Dr. M. Rehling; corresponding secretary, Dr. A. Stein, and treasurer, Dr. S. Breitenfeld.

**Raising Money for Cripples.**—A ten-day campaign is being conducted by Dr. Burr Burton Mosher for the purpose of raising $100,000 for the House of St. Giles the Cripple, which is the only orthopedic hospital on Long Island. It is announced that up to November 29, $71,246 had been raised.

**Fined for Milk Adulteration.**—The McDermott Dairy Company has been fined $1,000 for adulterating milk. The defense offered by the company was that the adulteration was done by a discharged driver. The court held that this was not an extenuation of the offense as the company was responsible for the acts of its employees.

**New Dispensary Now Ready.**—The New York Dispensary has just opened its new building in Spring Street. The original New York Dispensary was founded in 1790 at Five Points and has conducted a clinic for many years in Worth Street. The new building is thoroughly up to date and contains in addition to the usual modern equipment two rooms for the use of the social service department.

**Gift to New York Diet Kitchen.**—This organization, which dispenses pure milk to infants, has just received a gift of 500 shares of Great Northern stock, valued at $63,000, from Mr. and Mrs. Edward Tuck. The income from this fund will be used in maintaining the diet kitchen at 35 West 139th Street. The association had a deficit of $13,000 at the end of the fiscal year, but now sufficient funds are assured to carry on the work.

**Motherhood Not to Bar Teachers.**—Justice Seabury has rendered a decision in favor of Mrs. Bridget Peixotto, who had been suspended for absenting herself from school duties for the purpose of bearing a child. The court has expressed the opinion that the Board of Education has no right to dismiss a married teacher who absents herself from school to give birth to a child and that any attempt to do so would be against good morals.

**Unite to Fight Tuberculosis.**—The social service division of the Free Synagogue, the United Hebrew Charities, and the Montefiore Home have joined forces for the purpose of waging war on tuberculosis. A fund of $20,000 has been subscribed with which to begin work and each of the organizations joining in the work will make a further contribution. The Free Synagogue has pledged $10,000 annually to the work.

**Anniversary Meeting.**—The section on laryngology and rhinology of the New York Academy of Medicine celebrated its fortieth anniversary November 25. An address was made by Dr. Clinton Wagner of London, England, the founder of the New York Laryngological Society, which later became the laryngological section of the Academy of Medicine. Bryson Delavan made an address and presented the section with a bronze tablet.

**Personal.**—The will of the late Dr. Charles McBurney, recently filed at Stockbridge, Mass., disposes of the greater part of his effects to his children, but to the New York Physicians' Aid Society is given any rights, claims or demands that the testator may have against it.——Dr. William K. Jacobs has returned from Europe.——Dr. Francis B. Hart, Brooklyn, has been appointed coroner's physician for the Borough of Queens.——Dr. John McAllister is reported to be ill with septicemia, the result of stepping on a rusty nail.

**Concealed Cocain Stock.**—Through the evidence of a 17-year-old girl, Thomas De Lorenzo, a pugilist, has been arrested for traffic in cocain. Twenty-four packages of cocain were found concealed in a chamber underneath the floor of De Lorenzo's quarters. The evidence shows that three thousand ounces of cocain have been purchased during the last six months. The band of which De Lorenzo is the head paid $15,000 for the drug and sold this amount in small lots for approximately $90,000. The defendant was held in $5,000 bail.

**Montefiore Home Dedicated.**—The new buildings of the Montefiore Home and Hospital for Chronic Invalids at Gunhill Road and Jerome Avenues, were dedicated November 30. A reception was held in the institution by the president and directors from 11 a. m. to 1 p. m. and from 2 to 5 p. m. The medical department of this beneficent institution was organized by Dr. Simon Baruch in 1884. From its original twenty beds, it has now a capacity of 300 patients. Dr. Baruch served as chief of the medical staff for ten years, as consulting physician from 1894 to 1900 and since that time as honorary consulting physician.

**Midwives Must Have Diplomas.**—At a meeting of the Board of Health October 14, the following resolution relative to the practice of midwives was passed: *Resolved*, That the rules governing the practice of midwifery in the City of New York adopted by the Board of Health Nov. 8, 1907, be and the same are hereby amended so as to read as follows; the same to take effect on and after the 1st day of January, 1914: The applicant must be 21 years of age or upward, of good moral character, and able to read and write. She must be clean and constantly show evidence in general appearance of habits of cleanliness. The applicant must also present a diploma or certificate showing that she is a graduate of a school for midwives registered by the Board of Health of the City of New York as maintaining a satisfactory standard of preparation, instruction, and course of study, but the requirement of a diploma shall not apply to any person who is now or has been hitherto authorized to practice midwifery by the said board.

**Reorganization of the Department of Health.**—At a meeting of the Board of Health, Oct. 28, 1913, resolutions were adopted effecting a reorganization of the department by which divisions, which started as insignificant items in the work of the department and have grown to importance, become bureaus. The department now consists of the following bureaus: Bureau of general administration, under Eugene W. Scheffer; sanitary bureau, under the sanitary superintendent; bureau of infectious diseases, under Dr. John S. Billings; bureau of child hygiene, under Dr. S. Josephine Baker; bureau of hospitals, under Dr. J. R. Wilson; bureau of laboratories, under Dr. William H. Park; bureau of food inspection, under Dr. Marion B. McMillan; bureau of records, under Dr. William H. Guilfoy. The bureau of infectious diseases will now include the division of contagious diseases, tuberculosis, venereal diseases, veterinary diseases, institution inspection, typhoid fever, nurses and the diagnosis laboratory. The bureau of child hygiene will include midwife and foundling inspection, institutions and day nurseries, medical inspection of schools, employment certificates, infants' milk stations and children's clinics. The bureau of food inspection will comprise the inspection of meats, fish, vegetables and drugs, city and country milk inspection and the inspection of pasteurizing plants. The chief executives of the bureaus will be required to report directly to the commissioner of health and will be held responsible for the conduct of the work and the efficiency of the employes under their direction.

## NORTH CAROLINA

**Personal.**—Dr. P. B. Orr has been elected health officer of the recently incorporated city of West Asheville.——Dr. Thomas S. Burbank, Wilmington, is reported to be ill with disease of the kidneys.

**Fire Damages Medical Building.**—The early morning fire in the rear section of the Judson Payne Leonard Medical Building at Shaw University, Raleigh, November 8, did damage amounting to about $5,000.

**County Bulletin.**—The health authorities of Sampson County have issued the first number of the Sampson County Health Bulletin. Dr. Cooper, the county physician, is the director, and the bulletin is intended to teach the prime importance of sanitation.

**Monument to Dr. Kerr Unveiled.**—On November 13, the monument erected to Dr. Charles Stevens Kerr by his friends and neighbors at Kerr, was unveiled. Eulogistic addresses were made by Mr. W. S. Robinson, Mr. George R. Ward and Dr. John M. Faison.

**Get-Together Meeting.**—A joint meeting of the councilors of the Medical Society of the State of North Carolina and the State Board of Health was held in Greensboro, November 19, to study methods and devise plans to render more efficient the work of the county medical societies and further to conserve in every way possible the public health interests of the state.

**Hospital Notes.**—The Corcoran Hotel property, Durham, has been leased by the incorporators of Mercy Hospital, who announce that the institution will open January 1.——The corner-stone of the Wilson Hospital and Tuberculosis Home for Negroes was laid with appropriate ceremonies November 27. The principal address was made by W. S. Rankin, secretary of the city Board of Health.——The Red Cross Society of Wilmington announces the completion and opening on December 1 of its sanatorium for tuberculosis, located 2 miles below Wilmington. The institution can accommodate forty patients.

## PENNSYLVANIA

**New Officers.**—Franklin County Medical Association at Chambersburg, November 18: president, Dr. A. B. Sollenberger, Waynesboro; secretary, Dr. John J. Coffman, Scotland.

**Personal.**—Dr. Frederick E. McN. Howell has been appointed chairman and Dr. Daniel N. Bertolet, a member of the committee on health and sanitation of the Reading Chamber of Commerce, which has been established to take up the matter of housing and sanitary conditions.

**Plan for Care of Dependents.**—A constructive program for the care and prevention of dependents in Pennsylvania was announced November 28, by Dr. Charles H. Frazier, president of the Public Charity Association. These plans include a central directing body, such as the State Board of Charities. The recent conference held between the representatives of the State Board of Charities and the Public Charities Association, under the auspices of Governor Tener, was to further the cooperation of the state local authorities in Pennsylvania, for the purpose of making the plans operative and successful. Dr. Frazier discussed the possibilities of cooperation in the care and prevention of tuberculosis.

**Honey Impure.**—Judge Holland, of the United States District Court, is hearing testimony in a food case considered most important by the government because the outcome may change the present method of labeling honey. The question to be determined is whether or not six cases of honey seized by the federal food inspectors in this city shall be ordered destroyed on the grounds of being adulterated. According to William H. Jenkins, in charge of the food inspection bureau, the honey was shipped by the Excelsior Honey Company, of New York, 1912. It was seized before being delivered, after samples analyzed by government chemists indicated it contained 60 per cent. of added invert sugar.

### Philadelphia

**Recognizes Long Service.**—In recognition of his thirty-three years of service to the city as a health officer, Capt. Charles F. Kennedy, first and only disinfector in the employ of the city in 1880, was given a banquet and reception by about fifty employees of the Bureau of Health, November 20.

**Baby-Saving Show Opened.**—The Northern Liberties Baby-Saving Show was opened December 3, in the Friends' Neighborhood Guild, Fourth and Green Streets. The show is under the auspices of the Child Federation. It is estimated that 25 per cent. of the mortality in that part of the city is infantile and that the majority of these deaths are preventable.

**Mütter Lecture.**—The Mütter lecture on Surgical Pathology will be delivered by Dr. Robert C. Coffey, Portland, Ore., in the Thompson Hall of the College of Physicians of Philadelphia, at 8:30 p. m., December 12, on "Chronic Constipation Considered From the Embryologic Anatomical and Experimental Standpoints," illustrated by lantern slides and drawings. After the lecture a reception will be given to Dr. Coffey at the Hotel Rittenhouse.

**Seizure of Impure Food.**—On November 20, as a result of the work by state and city veterinarians and food inspectors, between 11,000 and 12,000 pounds of fish, game, and poultry were condemned as unfit for food and sent to local fertilizing works, where it was destroyed. The condition of the food products was blamed directly on the abnormally warm weather by the officials. The quantity seized represented shipments from Southern and Western points, valued at several thousand dollars.

**Baby Improvement Show.**—Almost 600 babies have been registered in the baby improvement contest being held by the Child Federation at their headquarters, Tenth and Bainbridge Streets. Babies showing the greatest improvement in two months will receive prizes of $25.00, $15.00 and $10.00. Babies when entered are given a physical examination, which is repeated the last Monday of the contest, and careful records are made of all data revealed. Normal infants between the age of 1 month and 2 years are eligible. The purpose of the contest is to stimulate greater interest in the welfare of infants and spread hygienic knowledge.

**Personal.**—Dr. J. Solis Cohen has been elected an honorary member of the Philadelphia Laryngological Society.——Dr. Arthur J. Davidson has been appointed orthopedic surgeon to the Jewish Hospital.——Dr. Charles H. Frazier had conferred on him the honorary degree of Doctor of Science, by Hobart College, Geneva, N. Y., recently.——Dr. Frances J. Heath, who is to teach surgery and anatomy in the Union Medical College, Peking, China, has started for her post of duty.——Dr. William Campbell Posey, who has been seriously ill with pneumonia, is very much better and his complete recovery is expected.——Dr. D. Braden Kyle is seriously ill with pneumonia at his home.

**For Greater Efficiency in Hospitals.**—A committee of six members of the Philadelphia County Medical Society presented a report, November 26, recommending a system by which it will be possible to increase the efficiency of hospitals in this city, reduce the cost of maintenance and render a greater aid in the prevention of sickness. The members of this committee are: Drs. Edward Martin, Charles Penrose, George E. De Schweinitz, Wilmer Krusen, John D. McClean, Joseph F. Neff, and Robert LeComte. The plan suggested includes a development of community system for hospital social service. The appointment of efficiency at each hospital, the use of uniform methods of accounting, a preparation of statistics, a development of "follow-up" work, by which the progress of patients toward complete recovery may be known after they have left the hospital. There are nineteen hospitals in this city which have one or more social service workers employed, and instead of increasing the expenditure of the hospital this department makes it possible to discharge a patient at the beginning of convalescence. The report further says: "A hospital is efficient if it performs its functions—the care of the sick, the prevention of disease, the research work and the education of doctors, nurses and the public—thoroughly and with the least possible waste of labor, materials and money. We believe that if the hospitals of Philadelphia should make a united effort to discover and eliminate all of the various forms of preventable waste which undoubtedly exist at the present time it would not only reduce the cost, but greatly increase the efficiency of these institutions." Cooperation of the State Board of Charities is urged, especially in getting hospitals to adopt the uniform system of accounting which has been prepared for the committee by W. B. Hadley, chief accountant in the office of the city controller.

## GENERAL

**Seaboard Physicians to Meet.**—The annual meeting of the Seaboard Medical Association, composed of members of the profession in North Carolina and Virginia, will hold its annual meeting in Norfolk, Va., December 9 to 12, under the presidency of Dr. J. E. Rawls, Suffolk.

**Duluth and Superior Physicians Meet.**—At the Interurban Academy of Medicine held at Superior, November 19, Dr. C. D. Conkey, Superior, was elected president; Dr. C. F. McComb, Duluth, vice-president; Dr. Andres G. Hoyde, Superior, secretary-treasurer, and Dr. Homer Collins, Duluth, censor.

**Southern Medical Women Organize.**—The Association of Southern Medical Women, dedicated to the furtherance of public health campaigns in the South, was inaugurated, November 18, at Lexington, Ky., as an auxiliary to the Southern Medical Society. Dr. Lillian H. South, Bowling Green, Ky., was elected president and Dr. L. Rosa C. Gantt, Spartanburg, S. C., secretary-treasurer.

**Death Abroad.**—In addition to the deaths noted by our correspondent, the following is reported: Edward Nettleship, F.R.C.S., Eng., 1870; F.R.S.; eminent as an ophthalmologist; consulting surgeon to the Royal London Ophthalmic Hospital; consulting ophthalmic surgeon to St. Thomas Hospital; one of the founders, surgical secretary and president of the Ophthalmological Society of the United Kingdom; died at his home in Hindhead, October 30, aged 68.

**Bubonic Plague and Yellow Fever.**—Consul Baker at Guayaquil, Ecuador, reported to the state department under date of

November 6, that there were 112 cases of bubonic plague in Guayaquil and that yellow fever was on the increase. Under date of November 13, fifty-two additional cases were reported at that point.——Under date of November 12, it was reported that the California State Board of Health had ordered the director of the State Hygienic Laboratory to Kennett, in that state, to investigate two cases of reported bubonic plague.

**Bequests and Donations.**—The following bequests and donations have recently been announced:

West Philadelphia Hospital, $5,000 by the will of Emily Sheetz, for the establishment of an emergency free bed.

Germantown Hospital, $5,000 by the will of Isabella T. Camblos.

Mercy Hospital, Kansas City, Mo., a donation of $25,000 by J. L. Loose, contingent on the securing of at least $200,000 to be used as a permanent endowment fund for new buildings.

Good Shepherd Hospital for the Insane, Quebec, $20,000; Jeffrey Hale Hospital $10,000 by the will of Hon. Sharples, Quebec.

St. Michael's Hospital, Toronto, $5,776; Hospital for Incurables $2,000, Hospital for Sick Children $3,000; Toronto General Hospital, $5,000 by the will of Eugene O'Keefe, Toronto.

**Meeting of the Physicians of the South.**—The Southern Medical Association held its seventh annual meeting in Lexington, Ky., November 18 to 20, under the presidency of Dr. Frank A. Jones, Memphis, and elected the following officers: president, Dr. Stuart McGuire, Richmond, Va.; vice-presidents, Dr. J. W. Jervey, Greenville, S. C., and F. H. Clarke, Lexington, Ky.; secretary-treasurer, Dr. Seale Harris, Mobile, Ala. (reelected). Richmond, Va., was selected as the place of meeting for 1914. The following section officers were appointed: Eye, Ear, Nose and Throat—Dr. Homer Du Puy, New Orleans, chairman; Dr. S. Nelson, Memphis, secretary; Hygiene and Preventive Medicine—Dr. R. M. Cunningham, Ensley, Ala., chairman; Dr. W. S. Leathers, University, Miss., secretary.

**The American Association of Immunologists.**—This society was organized June 15 at Minneapolis, Minn., with forty-one charter members, all of whom have been pupils of Sir Almroth E. Wright of London. The objects of the society are: "To unite the physicians of the United States and Canada who are engaged in the scientific study of immunology and bacterial therapy. To study the problems of immunology, and to promote by its concerted efforts scientific research in this department. To spread a correct knowledge of vaccine therapy and immunology among general practitioners." The officers temporarily chosen are: president, Dr. Gerald B. Webb, Colorado Springs, Colo.; vice-president, Dr. George W. Ross, Toronto, Canada; treasurer, Dr. Willard J. Stone, Toledo, Ohio; secretary, Dr. Martin J. Synnott, Montclair, N. J., and council, Drs. A. Parker Hitchens, Glenolden, Pa.; Oscar Berghausen, Cincinnati; J. E. Robinson, Temple, Tex.; Campbell Laidlaw, Ottawa, Canada, and Henry L. Ulrich, Minneapolis. The first annual meeting of the society will be held June 1, 1914, at Atlantic City, N. J.

**Infectious Diseases.**—During the fall the various infectious diseases have been very prevalent throughout the country, in some places small epidemics occurring. Cases of diphtheria and small-pox have perhaps occurred in greatest numbers. For the last week in November diphtheria was reported, among others, from the following places: Hamilton, O., 232 cases; Duluth, Minn., 40 cases, traced to a dairy; La Rue, O.; Hastings, Neb., where one school was closed; Suffield, Conn.; Worcester, Mass.; Antietam Furnace, Md., school closed; La Crosse, Wis., school closed; Detroit, where an antitoxin campaign was urged by the health board; Brenham, Tex., one county school closed; Greencastle, Ind.; Warsaw, Ind.; Waddy, Ky.; St. Paul, Minn., 140 cases during November; one small epidemic was traced to a certain dairy. November 19 the offices of the State Board of Health at Jackson went into voluntary quarantine on account of the discovery of diphtheria infection in the throats of the laboratory staff, caused by the careless sending in of specimens by physicians throughout the state, similarly to the trouble in the state board office in Atlanta, Ga., where a number of cases of the disease occurred, compelling the closing of the office.

Small-pox: At Oklahoma City 12 cases were reported; from Pennsylvania at Johnstown, Altoona, Wilkes-Barre, Reading, Huntington, Bowmanstown and Philadelphia; Milwaukee, Wis., where 21 cases were reported; De Pere, Wis.; Kansas City, Mo.; in the jail at Opelika, Ala., court postponed; Salt Lake City, 29 cases; Niagara Falls, two schools closed; Mt. Horeb, Wis., 14 cases; people defied health board order to vaccinate; Norway, Kan., school closed; Chicago, 11 cases occurred in Bernarr McFadden's "Healthatorium," none of whom had been vaccinated; at Joliet an epidemic with 40 cases occurred.

Measles: Riverbank, Cal., 25 cases in the grammar school; Rickardsville, Iowa, schools closed; Walla Walla, Wash., 50 per cent. of pupils afflicted; at Kodiak, Alaska, and the Afognak Islands, 100 natives have died from epidemic measles.

Scarlet Fever: Sunbury, Pa., 55 cases reported; some schools closed; Thurston, N. Y., schools closed; Paducah, Ky., strict quarantine enforced on account of epidemic; Everett and Malden, Mass., pest-house opened to accommodate the patients; 50 cases in Everett and some schools closed; Wapping, Conn.; Lynchburg, Va., quarantine lifted from the Miller Female Orphanage, where 18 cases but no deaths occurred.

Chicken-pox: Twenty cases reported from Topeka; Canton, Ill.; Wilkes-Barre, Pa.; Little Rock, Ark.

Trachoma: Columbus, Ind., 49 cases reported among schoolchildren in the county; Florin, Cal., 6 cases found among Japanese schoolchildren.

## CANADA

**Personals.**—Dr. Herbert J. Patterson, London, England, addressed the Academy of Medicine, Toronto, the evening of the 24th of November, on stomach surgery.——Dr. Oskar Klotz, professor of pathology and bacteriology, University of Pittsburgh, addressed the Academy of Medicine, Toronto, the evening of the 2nd of December, on "The Triple Alliance—Heart, Kidney and Arterial Disease."

**Infant Mortality in Montreal.**—The infant mortality of Montreal is practically double that of any other city in North America. Montreal with a population of 568,000 had 5,534 infant deaths in 1910, while Toronto with a population of 410,000 had 1,420. In 1912 in Montreal the deaths decreased, numbering 4,835, while in Toronto they increased and amounted to 1,584. The rate per thousand for the three years in Montreal was 9.2, while in Toronto it was 3.6. During the present year up to August 15 there had been registered in Montreal 4,172 infant deaths.

**Hospital News.**—Toronto is considering establishing two new hospitals to serve the east and west ends of that city, the total cost of both institutions to be about $1,000,000. Sites for both have been selected and approved by Dr. Bruce Smith, inspector of hospitals for Ontario and Dr. Chas. J. C. O. Hastings, medical officer of health for Toronto. It is likely that the city will submit by-laws at the coming municipal elections to provide $250,000 as a start for each institution. Dr. Bruce Smith says Toronto needs hospital accommodation for at least 500 more beds.

At the annual meeting of the medical staff and the board of governors of the Western Hospital, Toronto, the medical staff vigorously protested against appointments of three chiefs of clinics made without their consent. Recently a fine new hospital building was completed and arrangements made whereby medical students from the medical department of the University of Toronto would receive clinical instruction. The university authorities required three services of 100 beds each, and it was over the appointment of the heads of these services that the trouble arose. The following officers were elected: Dean of the medical staff, Dr. Elias Clouse; secretary, Dr. Frank Trebilcock; medical superintendent, Dr. James McCullough.——During the year ended September 30, 1,243 patients were treated in the Montreal Maternity Hospital, an increase of 250 patients over the previous year. The benefits of the institution were bestowed on twenty-five nationalities. The staff of nurses now number twenty-one.

## LONDON LETTER

*(From Our Regular Correspondent)*

LONDON, Nov. 15, 1913.

### The London Medico-Psychological Clinic

Excepting at Liverpool there is no clinic in England for the treatment of incipient mental disease. One has just been inaugurated in London termed the London Medico-Psychological Clinic. At the inaugural meeting Lord Sandwich, who was evidently chosen to preside in consequence of his interest in the subject, gave an address in which he "put his foot in it" with a vengeance. Having expressed his belief in the immense power exercised by the mind over the body he said that although he knew nothing of medical science he had had great experience in healing. During the South African War he received sixty officers into his country house and there had never been a doctor or nurse in the place. He himself had acted in both capacities toward his guests and had been both surprised and gratified by his success. There were few serious maladies that he had not treated, and he had never failed to relieve persons in the agonies of pain. He had attended people in palaces, in cottages, in hospitals and in homes. His patients had included a Hindu monk in his monastery, a Mohammedan in his mosque and a Hindu princess who had traveled 500 miles to see him. He had often been asked to explain his power, but he had nothing to explain. He could only say what happened. He was convinced, however, that many other persons possessed similar power, if not to the same extent at least in lesser degree. In the proposed clinic there would be an opportunity for them to exercise it with great usefulness.

Other speakers followed. Miss Constance Long, a woman physician, said that many doctors had successfully practiced psychotherapy, but up to the present there had been no provision for the treatment of the poor. The Medico-Psychological Clinic would supply this and also provide opportunities for investigation of disease. The patients would include persons suffering from depression, insomnia, loss of sensation, the drug habit, morbid attention to bodily ailments, etc. The treatment would consist of persuasion, suggestion, reeducation, psychanalysis, induced sleep and hypnotism. The clinic would not be in opposition to orthodox medicine but supplementary to it, and forces could be joined with medical practitioners in a suitable building. Dr. Spearman, professor of psychology at University College, said there could be no doubt that science would gain from the formation of the new clinic. There was a growing interest in and demand for psychotherapy which could not be disregarded. Some years ago the subject had been treated with derision, but to-day this had ceased, and knowledge had been gained. Dr. Maurice Craig, F.R.C.P., physician for mental diseases and lecturer to Guy's Hospital, a well-known alienist, said that there was no proper provision in England for patients suffering from incipient mental disorder. They were left to struggle on until ready to be admitted into lunatic asylums, though a little timely treatment would have restored them. These unfortunates were by no means always the derelicts of society, but were frequently highly endowed and gifted.

As might be expected, the extraordinary claims of the chairman, a layman, to marvelous healing powers at a meeting in which the cooperation of the profession was necessary, had a sequel. The physicians concerned have written to the press saying that they had been compelled to dissociate themselves from the occult powers claimed by Lord Sandwich, who has terminated his association with the clinic. They add that they profess nothing but ordinary medical knowledge acquired in the ordinary way, and hope that the clinic will attract the physicians who wish to learn practical psychotherapy. The whole of the healing art was cradled in superstition, and in the minds of many psychotherapy is still tinged with charlatanism from which the clinic would help to dissociate it.

### Tuberculosis among Natives of South Africa

A parallel to the prevalence of tuberculosis among the negroes of the United States seems to be coming into existence in South Africa, where the same race is being brought into contact with European civilization. At the recent meeting of the South African Medical Congress Dr. D. Melville, who has for sixteen years resided in the heart of the "native territories" and acquired considerable knowledge of the manners and customs of the natives, said that deaths from tuberculosis occurred at all ages among the natives, excepting children. and were particularly frequent among young adults. The disease appeared to be responsible for a decline in the native population. A rapid increase of this population was noted in the census of 1904, but was not maintained in 1911, and a further drop would be shown in 1921. In three districts, which he knew well, the census gave the total native population as 81,272 in 1891 and 104,346 in 1904—an increase of 23,074, at the rate of 1,775 per annum. In 1911 the population was 110,358, an increase of 6,012, at the rate of 858 per annum. Thus the rate of increase had fallen by one-half, though during the period referred to the birth-rate had remained stationary. Tuberculosis was undoubtedly on the increase, for on going over the first 3,000 cases he treated in 1897 only 1 per cent. were found to be tuberculous, while the first 3,000 cases treated in 1912 showed 40 per cent. of tuberculosis. Of the tuberculous affections lung disease was easily first and glandular disease second, while affections of bones and joints were not numerous. The natives could be divided into two great classes—the red or blanket Kaffir, and the dressed Kaffir who adopted European clothing. In 1897 tuberculosis was much less prevalent in the blanket Kaffir, and this still held good but not to the same degree. In the overcrowded, dark, dirty and damp huts, never ventilated and never open to the sunlight, the disease was propagated. Where could the bacillus find better conditions for growth? Natives were great smokers, spit freely on the floors, and one pipe was passed from one to another.

### The Bacteriology of Food-Poisoning

In a report to the local government board Dr. Savage communicated some important observations on "ptomain poisoning," as it used to be called, but which modern investigation is showing to be due to bacterial infection. Dr. Savage points out that the bacteria concerned in food infections can be included roughly in three groups: (*a*) the Gaertner group of bacilli, (*b*) non-Gaertner aerobic bacilli, such as *Bacillus proteus* and *B. coli*, and (*c*) *B. botulinus*. In the majority of recorded outbreaks of food-poisoning in which fatal cases have occurred, one or other of the Gaertner group of bacilli seems to have been the infecting organism. The Gaertner group of bacilli is a subgroup of the large coli-typhoid group, its members occupying an intermediate position between the chemically active coli group and the chemically inert typhoid group, and consisting of (1) *B. enteritidis*, which includes not only many of the Gaertner bacilli isolated in cases of food poisoning but also many of the strains of *B. typhi murium;* (2) *B. suipestifer*, with which one must associate some of the *B. typhi murium* strains, probably *B. psittacosis*, and (3) *B. paratyphosus* B. Sausage and ham are the commonest two sources of botulism. From the anaerobic character of the bacillus and the fact that outbreaks of botulism have never followed the eating of food in a fresh state, botulism must be produced by an invasion of food by *B. botulinus* only when suitable anaerobic conditions are provided, for example, when a ham is stored at the bottom of a pickling cask and entirely covered by the pickling solution. Van Ermengem states that the disease has never occurred when the food has been properly cooked as *B. botulinus* and its toxins are easily destroyed by heating. The *B. botulinus* will not grow in mediums containing more than 6 per cent. of sodium chlorid and it is unlikely, therefore, that any meat would develop *B. botulinus*, even if stored under anaerobic conditions, if a pickling solution containing 15 per cent. of salt were used.

## PARIS LETTER

*(From Our Regular Correspondent)*

Paris, Nov. 13, 1913.

### Centenary of the Discovery of Iodin

November 9 the centenary of the discovery of iodin was celebrated. It was in November, 1813, that Bernard Courtois, who was born Feb. 15, 1777, at Dijon, read before the Académie des sciences a note entitled "Discovery of a New Substance in Sea-Wrack." Many scientific and medical men of prominence went to Dijon to take part in the celebration. A commemorative tablet was placed on the house in which Bernard Courtois was born. Afterward a session was held in the hall of the Académie de Dijon. Camille Matignon, professor of inorganic chemistry at the College of France, read an interesting paper on the discovery of iodin. During the troublous times of the eighteenth century the problem of nitrogen, or rather of potassium nitrate, demanded the attention of nations and of chemists. The old gunpowder was a mixture of potassium nitrate, sulphur and carbon, but the potassium nitrate constituted three-fourths of the mixture. The natural supply of saltpeter was insufficient for the needs of the various nations. A *salpêtrière* (manufactory of saltpeter) was founded at Dijon, and in the preparation of saltpeter Bernard Courtois noted, during the evaporation of the solution of sodium nitrate leached from the ashes of marine plants, that the copper caldrons used for the operation soon became perforated. In trying to find out the cause, he found that the copper combined with a substance the nature of which was unknown to him. He was able to isolate from the mother-waters of sea-wrack soda a new substance to which Gay-Lussac gave the name of "iodin." The first therapeutic application of iodin was made by Coindet of Geneva in 1820. He published a memoir on the discovery of a new remedy for goiter. From 1830 to 1840 the iodin industry was founded. More than twelve hundred families along the shore of the Cottentin and of Brittany were occupied in gathering, drying, grinding and burning sea-weeds. Later iodin was obtained from the saltpeter of Chile, and the rich layers of potassium and bromin salts from Stassfürt. To-day the greatest part of the iodin consumed comes from Chile. While in 1875 the production of iodin throughout the world did not exceed 250,000 kg., it had risen in 1900 to 590,000 kg., and of late amounts to about 450,000 kg. France produces only about 59,000 kg.

### Dangerous Colon Reactions

November 11, Dr. Albert Mathieu, physician of the hospitals of Paris, read before the Académie de médecine a paper on colic reactions. Under this name he designates reflex phenomena of colonic and sigmoidorectal origin which, under their most simple aspect, take the form of nauseas, vomitings, vertigoes or fainting, occurring among constipated persons at the time of an evacuation of the bowels after a period of several days of fecal retention. In some cases the complications occur at each such crisis, and sometimes are serious. Thus, in a young girl of 23 the vomiting had caused suspicion of the existence of chronic appendicitis, and the appendix had been removed. Later, the existence of a gastric or duodenal ulcer had been suspected. Moreover, there had been a hematemesis a year before that. One day, after a glycerinated enema, at the very moment of dejection, there occurred abruptly a sharp abdominal pain, vomiting, a serious condition of collapse with cold extremities, facies abdominalis and a rapid filiform pulse, so that a gastric perforation was feared. An exploratory laparotomy performed three hours later showed that there was no such perforation. Only adhesions were found and a duodenal scar, no doubt the results of former ulcers. A gastro-enterostomy was performed. A month later there was a similar crisis following another such dejection. In another case, that of a woman under treatment for chronic colitis, there was a serious collapse following a mucilaginous injection to which zinc oxid and bismuth subgallate were added, according to the formula used by the Mathieu service. The collapse was combated by injections of caffein and lasted three hours.

### A Medal Presented to Dr. Roux

To-morrow the twenty-fifth anniversary of the foundation of the Pasteur Institute will be celebrated in the presence of the President of the Republic (The Journal, Oct. 4, 1913, p. 1307). The pupils and friends of Dr. Roux, director of the institute, have arranged to present him before the celebration with a medal bearing his own portrait.

### Honor to the Memory of Dr. Lucas-Championnière

A petition to have a street in Paris named after Dr. Lucas-Championnière has received the signatures of all the members of the Académie de médecine to which it has been presented. The same proposition was made in the municipal council at the last session and was reported on favorably.

### *A Limitation of the Number of Licenses for the Sale of Liquor*

In several departments, the prefects have forbidden giving licenses for the sale of liquors within a certain radius from 200 to 300 meters around churches, schools, cemeteries, barracks and hospitals.

## BERLIN LETTER

*(From Our Regular Correspondent)*

Berlin, Nov. 14, 1913.

### Personal

Professor Doutrelepont of Bonn, who was formerly director of the dermatologic clinic, celebrated, October 26, the fiftieth anniversary of his doctorate.

Professor Morawitz of Freiburg has received a call to Greifswald as director of the medical clinic.

Professor Hotz of Würzburg has gone to Freiburg as successor of the deceased Professor Goldmann.

November 6, Professor Trautmann, department head at the Hygienic Institute of Hamburg, died after a short illness at the age of 38. He had published numerous articles on meat poisoning, plague, meningitis, sterilization of milk, etc.

November 5, Professor Ponfick, formerly manager of the Pathologic Institute at Breslau, died at the age of 69. He was born Nov. 3, 1844, at Frankfort a.M., and after studying at Tübingen, Freiburg and Heidelberg, he became first an assistant of C. O. Weber, the Heidelberg surgeon, and afterward went to Recklinghausen at Würzburg for pathologic study, and came in 1868 to Berlin as assistant to Virchow in the Pathologic Institute. From here he was called to Rostock as regular professor in 1873. His work as professor was interrupted for some time by a journey of investigation which he made to Egypt, Nubia and Palestine as companion of the hereditary grand duke of Mecklenburg. In 1876 he accepted a call to Göttingen, and from there in 1878 he went to Breslau, where he acted as director of the Pathologic Institute until the spring of this year.

He was prominent as a teacher at the Breslau University, and as a scientist he published a large number of important articles. Among these is a series on transfusion, especially on the changes that the blood of a sheep undergoes when introduced into the circulation of man. He also wrote on mushroom poisoning and on the pathology of the liver and pancreas, on myxedema, on middle ear disease in small children, and on actinomycosis, which was at that time a new infectious disease.

The editor of the *Berliner klinische Wochenschrift*, Dr. Hans Kohn, has received the title of professor.

Professor Schuchardt, director of the nerve clinic at Rostock, died November 7, aged 66. He was assistant at the medical clinic at Strasburg under Leyden and Kussmaul, and later became a member of the faculty at Bonn as assistant in the psychiatric clinic. In 1895 he was elected professor of psychiatry at Rostock. His works are concerned with his specialty, particularly with the public care of the insane.

### The Eleventh German Conference on Tuberculosis

The eleventh tuberculosis conference under the patronage of the empress began October 22 in the Parliament House in Berlin.

#### SPECIAL TUBERCULOSIS DISPENSARIES

The first subject discussed was the special tuberculosis dispensaries (Fürsorgestellen für Lungenkranke). In the discussion, much interesting matter was presented with reference to the organization of tuberculosis dispensaries in different countries, such as Sweden, where the care of tuberculosis is far advanced, and Austria, where they are just beginning to lay a greater stress on this question. It was further discussed whether the physician connected with the special dispensary should be at the same time the director. The opinion of the conference inclined to the view that in the smaller places the physician may readily direct the technical matters and the details of the management, but in larger cities it is better to have a special official to take charge of these matters. This is especially favorable in bureaus established by the community where the medical representative of the city government may act at the same time as the chairman of the assistance bureau.

One of the representatives of the Krankenkassen warned against expecting the insurance societies to devote more and larger sums to the prophylaxis of tuberculosis; the Krankenkassen have so many demands of this sort that unless the fees are raised, any additional efforts on their part along this line are scarcely to be thought of.

#### SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS

Professor Brauer of Hamburg said that in the surgical treatment of tuberculosis a number of measures have given little result. On the other hand, the treatment of pulmonary tuberculosis by rest and compression of the lung tissue has proved successful. This is accomplished either by an artificial pneumothorax or by a plastic operation to reduce the size of the thorax. The simplest measure, when the pleural cavity is free, is the injection of air between the costal pleura and the lung, a measure which of late years has been widely adopted and with a careful selection of patients and proper technic has proved very useful and relatively free from danger. In case of pleural adhesions, various operative measures may be considered: circumscribed depression of the thorax wall, the purpose of which is to promote the already existing tendency of the lung to shrivel; the extensive extrapleural thoracoplasty recommended by Brauer, or the method of intrapleural thoracoplasty (Schede). It is very important that the indications be very strictly followed in regard to the general condition of the patient, complications, and especially the condition of the lung of the other side. Partial collapse and immobilization of the lung may be secured, aside from the Quincke-Spengler partial extrapleural thoracoplasty, by the freeing of the adherent apex of the lung. This procedure is especially successful by the method of Tuffier of Paris. He fills the space left by the liberation and depression of the upper lobe by implanting living adipose tissue. The process of Baer of Davos founded on this method attempts to fill the space by the injection of paraffin. This method is somewhat dangerous but may under some circumstances lead to good results. The paralysis of the diaphragm by cutting the nerve immobilizes the lower segments of the lung. Especially as a supplement to extrapleural thoracoplasty, benefit may be derived by this technic, as Sauerbach, Oelecker and others have shown. Brauer said in conclusion that one should not be led to overestimate the value of the method in consequence of the good results in individual cases, and, further, that the careful selection of suitable cases must be emphasized.

## Marriages

George Driver Brogaw, M.D., Pilares de Nacozari, Sonora, Mexico, to Miss Margaret Butler of Washington, D. C., November 18.

Wilhelm Ludwig Baum, M.D., to Mrs. Mervyn Winston Lawrence, both of Chicago, in New York City, November 24.

Corbin Jay Decker, M.D., U. S. N. (ret.) Philadelphia, to Miss Katherine Mason of Asheville, N. C., December 3.

Joseph D. Ely, M.D., Hudson, Mich., to Mrs. Ellen Ford Van Buskirk of Fayette, Ohio, at Toledo, November 8.

Arthur Woodward Booth, M.D., Elmira, N. Y., to Miss Jeannette Van Cleef of Ithaca, N. Y., November 19.

Andrew Culloden Panton, M.D., to Mrs. Florence Merges Carlock, both of Portland, Ore., November 15.

Harold T. Allison, M.D., Heppner, Ore., to Miss Olive J. Lockwood of Portland, Ore., November 16.

William Roy Van Duzer, M.D., Pasey, Iowa, to Miss Nora J. Brinton of Stuart, Iowa, November 20.

John Clifton Anthony, M.D., Birmingham, Ala., to Miss Mae Smith of Ozark, Ala., November 19.

Samuel Greenburg, M.D., to Miss Anna Ruth Matzkin, both of Brooklyn, N. Y., November 11.

Harry Troy Evans, M.D., Springfield, Mo., to Miss Edna F. Mann of St. Louis, November 17.

John C. McClenathan, M.D., to Miss Della Barnes, both of Connellsville, Pa., November 24.

Calvin Randolph Marshall, M.D., to Miss Grace Loomis, both of Indianapolis, November 15.

Charles E. Fawcett, M.D., to Mrs. Mabel Slater, both of Stewartville, Minn., November 19.

Olive M. Slate, M.D., Spokane, Wash., and John J. Maeny of Plains, Mont., November 18.

Ephraim Kirkpatrick Findlay, M.D., to Miss Irene Nelson, both of Chicago, October 22.

## Deaths

**Robert Lee Edwards, M.D.** New York University, New York City, 1894; a Fellow of the American Medical Association; formerly assistant in surgery in Cornell Medical College, New York City; later local surgeon of the Atlantic Coast Line Railroad at Darlington, S. C.; for the last six years a resident of Richmond, Va.; owner and physician in charge of the Southern Sanitarium; ophthalmologist, otologist and laryngologist to the Johnston Willis Sanitarium; died at his home in Richmond, November 12, from heart disease, aged 42.

**Charles Mayrant Rees, M.D.** Medical College of the State of South Carolina, Charleston, 1887; a Fellow of the American Medical Association; formerly professor of gynecology and obstetrics in the Charleston Medical School; professor of general and clinical surgery in his alma mater; first lieutenant, Medical Reserve Corps, U. S. Army; formerly president of the South Carolina Medical Association; died at his home in Charleston, November 15, aged 51.

**William Kendall Newcomb, M.D.** Rush Medical College, 1882; a Fellow of the American Medical Association; president of the Illinois State Medical Society in 1911, and once president of the Aesculapian Society of the Wabash Valley; one of the most esteemed and beloved practitioners of Central Illinois; attending physician to the Julia F. Burnham Hospital, Champaign; died at his home, November 25, from pneumonia, aged 56.

**Terence Lathrop Carroll, M.D.** Albany (N. Y.) Medical College, 1885; a member of the Medical Society of the State of New York; physician to the Albany Penitentiary; attending physician to St. Peter's Hospital and the South End Dispensary; died at his home in Albany, November 9, aged 49. Memorial services in honor of Dr. Carroll were held by the Albany County Medical Society, November 11.

**Russell F. Goodwin, M.D.** Rush Medical College, 1870; for many years proprietor of a sanatorium in Minneapolis; died in St. Barnabas Hospital in that city, November 15, aged 71, from injuries received two days before when he was struck by an automobile while attempting to board a street car.

**Charles Sumner Collins, M.D.** Boston University, 1875; formerly a member of the State Board of Health of New Hampshire and State Board of Lunacy and Charity; for several years a member of the state legislature; president of the Nashua Board of Education for twelve years and also president of the Nashua Board of Trade; died at his home, November 16, aged 60.

**Douglas Ayres, M.D.** Albany (N. Y.) Medical College, 1865; a Fellow of the American Medical Association; once president and first vice-president of the Medical Society of the State of New York; of the Montgomery County Medical Society; for many years president of the Board of Education of Fort Plain, N. Y.; died at his home, November 20, from myocarditis, aged 71.

**Lucien LaBland Brainard, M.D.** New York Homeopathic Medical College, New York City, 1874; a Fellow of the American Medical Association; for many years a member of the consulting staff of the Faxton Hospital, Utica, N. Y.; vice-president of the Little Falls (N. Y.) National Bank; died suddenly at his home in that city, November 18, from heart disease, aged 60.

**Henry Harrison Forline, M.D.** Kentucky School of Medicine, Louisville, 1861; Beaumont Hospital Medical College, St. Louis, 1887; formerly surgeon for the Missouri, Kansas and Texas Railroad, and while a resident of Chicago consulting physician to the Western Springs Sanitarium; died at his home in Los Angeles, August 8, from arteriosclerosis, aged 72.

**Edward Francis Denner, M.D.** College of Physicians and Surgeons, New York City, 1894; a member of the Medical Society of New Jersey and a leading practitioner of Paterson; for several years associate and consulting surgeon to St. Joseph's Hospital; died in that institution, November 14, from typhoid fever, aged 41.

**James H. McClelland, M.D.** Hahnemann Medical College, Philadelphia, 1867; president of the American Institute of Homeopathy in 1893-1894; professor of surgery in his alma mater in 1876 and 1877; president of the State Board of Health in 1895; died at his home in Pittsburgh, November 13, from heart disease, aged 68.

**Zachariah Taylor Miller, M.D.** Hahnemann Medical College, Philadelphia, 1877; a veteran of the Civil War; for many years professor of artistic anatomy in the Carnegie Institute of Technology; a member of the staff of the Pittsburgh Homeopathic Hospital; died at his home, November 14, from angina pectoris, aged 66.

**Simon James O'Neil, M.D.** New York University, New York City, 1887; formerly assistant in the department of obstetrics in his alma mater; for twenty years physician to the Rockaway Institute and House of the Good Shepherd, New York City; died at a hotel in Long Beach, November 14, from heart disease, aged 52.

**Henry Clay Beall, M.D.** Missouri Medical College, St. Louis, 1880; a Confederate veteran; for thirty-four years a practitioner of Carroll, Mo., and for ten years thereafter a resident of Cortez, Colo.; died at the home of his daughter in DeWitt, Mo., November 7, from pneumonia, aged 70.

**James Edwin Ray, M.D.** University of Pennsylvania, Philadelphia, 1860; a member of the Colorado State Medical Society; a pioneer practitioner of Crowley County, and a resident of Sugar City for fifty-six years; died in St. Mary's Hospital, Pueblo, November 12, from heart disease, aged 77.

**William Shippen, M.D.** Medical College of Virginia, Richmond, 1887; a member of the Medical Society of Virginia; for twenty years acting assistant surgeon in the Army; later city physician of Petersburg, Va.; died in the Petersburg Hospital, November 17, aged 52.

**Edwin R. Schwinn, M.D.** Chicago College of Medicine and Surgery, 1912; of Wheeling, W. Va.; aged 23; who went to Houston, Tex., to take the examination for license to practice medicine in that state, choked and died in that city, November 8, while eating supper.

**Edgar Clarence Collins, M.D.** Albany (N. Y.) Medical College, 1880; a Fellow of the American Medical Association; proprietor of the Collins Emergency Hospital, Springfield, Mass.; died in that institution, November 14, from angina pectoris, aged 55.

**W. Frank Clopton, M.D.** Tulane University, New Orleans, 1872; physician, cotton, planter, banker, head of the W. F. Clopton Mercantile Company and president of the police jury of St. Landry Parish, La.; died at his home in Morrow, November 18.

**John Kemper, M.D.** Illinois Army Board, 1864; Long Island College Hospital, Brooklyn, N. Y., 1867; surgeon of the Twenty-Eighth Illinois Volunteer Infantry during the Civil War; died at his home in Galesburg, Ill., November 28, aged 80.

**Charles E. Boult, M.D.** University of Buffalo, N. Y., 1892; president of the Board of Education of Honeoye Falls, N. Y., and one of the coroner's physicians of Monroe County; died suddenly at his home, November 7, from heart disease, aged 54.

**Albert W. Hendricks, M.D.** Eclectic Medical College of Pennsylvania, Philadelphia, 1871; one of the founders, and for many years surgeon, of the Home for Old Soldiers, Philadelphia; died at the home of his daughter in that city, November 19.

**John McIntyre Morrison, M.D.** Cooper Medical College, San Francisco, 1895; formerly a practitioner of Richmond and Loyalton, Cal.; died in the Roosevelt Hospital, Berkeley, Cal., November 16, from carcinoma of the stomach, aged 42.

**James Randolph Medlock, M.D.** Washington University Medical School, St. Louis, 1875; a Fellow of the American Medical Association; died suddenly at his home in Santa Ana, Cal., November 11, from cerebral hemorrhage, aged 76.

**Carl Fisch, M.D.** Missouri Medical College, St. Louis, 1893; a Fellow of the American Medical Association and a well-known pathologist and bacteriologist of St. Louis; died at his home, November 17, after a long illness, aged 54.

**William P. Jones, M.D.** Philadelphia University of Medicine and Surgery, 1861; assistant surgeon of the Forty-Second Pennsylvania Volunteer Infantry during the Civil War; died at his home in Philadelphia, November 18, aged 76.

**A. J. Clements, M.D.** University of Nashville, Tenn., 1858; for many years a practitioner of Glasgow, Ky.; a member of congress from Tennessee during President Lincoln's administration; died November 7, from pneumonia, aged 79.

**Philip Francis Xavier Ryan, M.D.** College of Physicians and Surgeons, New York City, 1901; for five years a medical examiner for the New York Life Insurance Company; died at his home in New York City, November 17, aged 37.

**Edward L. Braun, M.D.** Philadelphia College of Medicine and Surgery; for many years an alderman of Pittsburgh, Northside, but for five years a resident of Detroit; died at his home in that city, November 5, aged 58.

**Adolph J. Broell, M.D.** Northwestern University Medical School, 1892; of Chicago; a Fellow of the American Medical Association; died in the German-American Hospital, Chicago, November 30, from typhoid fever, aged 43.

**Frederick R. Hunt, M.D.** Northwestern University Medical School, Chicago, 1888; for several years a practitioner of Austin, Chicago; died suddenly at his home in California, August 30, from angina pectoris, aged 52.

**Thomas Hanson** (license, Ontario, 1891); a graduate of Victoria College, Medical Department, Coburg, Ont., in 1864; when too young to receive a degree; died at his home in Kenora, Ont., September 30, aged 67.

**James S. McFarland, M.D.** University of Edinburgh, Scotland, 1850; M.R.C.S., Edinburgh, 1850; for four and a half years a surgeon in the English Army; died at his home in Oil City, Pa., November 13, aged 80.

**David M. Nottingham, M.D.** Hahnemann Medical College, Chicago, 1881; formerly a member of the Michigan State Legislature; died at his home in East Lansing, Mich., November 11, from heart disease, aged 58.

**John Harvey Hill, M.D.** University of Pennsylvania, Philadelphia, 1867; a veteran of the Civil War; an expert on small-pox; died in his apartment in Baltimore, November 10, from ptomain poisoning, aged 70.

**Nelson B. Lafferty, M.D.** Starling Medical College, Columbus, Ohio, 1863; a member of the Ohio State Medical Association; a veteran of the Civil War; died at his home in Hillsboro, November 9, aged 73.

**John Walter Poston, M.D.** Eclectic Medical Institute, Cincinnati, 1873; Memphis Hospital Medical College, 1882; died at his home in Maury City, Tenn., about November 5, aged 63.

**Clarence T. Pope, M.D.** Louisville (Ky.) Medical College, 1873; for more than forty years a practitioner of Louisville; died at his home, November 13, aged 61.

**Paul Newlon, M.D.** University Medical College, Kansas City, Mo., 1908; died at his home in Lincoln, Kan., September 25, from typhoid fever, aged 29.

**Maria Gutterman Graff Scott, M.D.** University of Heidelberg, 1862; said to have been the first woman to practice medicine in Louisville; died at her home, November 13, from arteriosclerosis, aged 73.

**Lionel E. Bratton, M.D.** Memphis Hospital Medical College, 1896; University of Louisville (Ky.) 1900; a practitioner of Arkansas for twenty-five years; died at his home in Atkins, November 18, aged 49.

**James A. Koehler, M.D.** Ohio Medical University, Columbus, 1898; a Fellow of the American Medical Association; died at his home in Shelby, Ohio, November 13, from pernicious anemia, aged 40.

**Samuel S. Lytle, M.D.** University of Iowa, Iowa City, 1878; a pioneer member of the faculty of his alma mater; a veteran of the Civil War; died at his home in Iowa City, November 8, aged 71.

**Carl Lyle Hobson, M.D.** University of Pennsylvania, Philadelphia, 1910; a member of the Iowa State Medical Society, died at his home in Hampton, Iowa, November 14, from pneumonia, aged 27.

**Theophile A. Lafferty, M.D.** Michigan College of Medicine and Surgery, Detroit, 1903; of Detroit; died in the psychopathic ward of St. Mary's Hospital in that city, November 12, aged 34.

**Charles Ferdinand Durand, M.D.** University of Toronto, Ont., 1882; formerly acting medical superintendent of the Municipal Hospital, Buffalo; died in Toronto, November 10, from pneumonia.

**Charles Roy Stewart, M.D.** University of Nebraska, Lincoln, 1910; of Curtis, Neb.; was crushed under his overturned automobile near Curtis, November 2, and instantly killed, aged 27.

**William Pennington Mullin, M.D.** Hahnemann Medical College, Philadelphia, 1881; of Chestnut Hill, Philadelphia; died in St. Luke's Hospital in that city, November 14, aged 52.

**John B. Longshere, M.D.** Pennsylvania Medical College, Gettysburg, 1846; one of the oldest practitioners of New Jersey; died at his home in Camden, November 10, aged 92.

**Daniel B. Bobb, M.D.** Northwestern University Medical School, Chicago, 1864; for nearly half a century a practitioner of Dakota, Ill.; died at his home, November 14, aged 76.

**John Lawson Fleming, M.D.** University of Tennessee, Nashville, 1894; of Goodwin, Ark.; died in the Baptist Hospital, Memphis, October 19, from tetanus, aged 47.

**Christopher C. Hiatt** (license, Indiana, 1897); of Muncie, Ind.; a veteran of the Civil War; died in the Soldiers' Home, Lafayette, Ind., November 8, aged 83.

**Carl A. Coburn** (license, years of practice, Michigan, 1900); for about 40 years a practitioner of Michigan; died at his home in Homer, November 6, aged 73.

**George Bassett Sawtelle, M.D.** Hahnemann Medical College, Philadelphia, 1866; died at his home in Malden, Mass., November 14, from heart disease, aged 75.

**Ezekiel McNair, M.D.** Medical College of Georgia, Augusta, 1876; died at his home in Jeffersonville, Ga., September 16, from cerebral hemorrhage, aged 66.

**William Roscoe Dell, M.D.** Milwaukee Medical College, 1904; of Marinette, Wis.; died in a sanitarium in Kenosha, November 20, from nephritis, aged 34.

**Daniel Whitfield Carroll, M.D.** Vanderbilt University, Nashville, 1913; died at his home in Brock, Okla., October 28, from typhoid fever, aged 22.

**Lucien B. Abney, M.D.** Medical College of Ohio, Cincinnati, 1861; died at his home in Elizaville, Ky., November 6, aged 78.

**Denis Morin, M.D.** Hahnemann Medical College, Chicago, 1884; died at his home in Chicago, November 14, aged 72.

**Thomas Mahon Armstrong, M.D.** Victoria University, Coburg, Ont, 1860; died in Lloydtown, Ont., October 5, aged 76.

**Edward Roscoe Miller, M.D.** Boston University, 1887; died at his home in Leominster, Mass., October 17, aged 54.

**Arthur Marks, M.D.** Toledo (Ohio) Medical College, 1910; died at his home in Toledo, October 18, aged 31.

**Hiram Raleigh Kennedy, M.D.** University of Louisville, 1880; died at his home in Green Hill, Ala., October 8.

**Edward J. Fischer, M.D.** Rush Medical College, 1880; died at his home in Chicago, November 7, aged 65.

**George William Spears, M.D.** Boston University, 1876; died at his home in Boston, October 30.

**Frank G. Kimbrough, M.D.** University of Alabama, Mobile, 1890; died at his home in Salado, Tex., November 7.

# The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

## THE LACTIC ACID FERMENT PREPARATIONS IN N. N. R.

### Report of the Council on Pharmacy and Chemistry

The following report on the quality of the market-supply of the lactic acid ferment preparations described in New and Nonofficial Remedies has been authorized for publication.

W. A. PUCKNER, Secretary.

The frequently made assertions that the lactic acid ferment preparations on the market are worthless made it important to determine the quality of those admitted to New and Nonofficial Remedies. A control of these products appeared all the more desirable because past examinations of the market-supply showed these preparations to be most unreliable (THE JOURNAL Jan. 30, 1909, p. 372), and because their very nature makes deterioration likely.

Orders for one package of each of the lactic acid ferment preparations admitted to New and Nonofficial Remedies were therefore sent to three prescription pharmacists—one each in Chicago, Detroit and Indianapolis—with the request to take these from stock or to purchase them in the regular way. Also, specimens were ordered direct from the manufacturer.

None of the pharmacists could supply either bacillary milk or lactampoules. In answer to an inquiry the manufacturer states that so far these products are supplied direct only. One pharmacist sent a specimen of the Fairchild Culture of Bacillus Bulgaricus, and as this product had been sent to the council for inclusion with New and Nonofficial Remedies this specimen, and one sent by the manufacturer, were also included in the examination. Altogether, the following specimens were sent to the council's expert:

Fairchild Culture of Bacillus Bulgaricus, Fairchild Bros. & Foster. One specimen from manufacturer and one from pharmacist.

Lactic bacillary tablets, Fairchild Bros. & Foster. One specimen from manufacturer and three from pharmacists.

Lactampoules, Fairchild Bros. & Foster. One specimen from manufacturer.

Bacillary milk, Fairchild Bros. & Foster. One specimen from manufacturer.

Bulgara tablets, Hynson, Westcott & Co. Two specimens from manufacturer and three from pharmacists.

Massolin, Schieffelin & Co One specimen from manufacturer and two from pharmacists.

The following is the result of the investigation:

1. Preparations of Fairchild Bros. & Foster.

The Fairchild Culture of Bacillus Bulgaricus. Two samples were examined. These were both pure cultures and the bacilli were in good viable condition. The reactions on litmus-milk were typical. Sterilized milk coagulated promptly in less than twenty-four hours, forming a good, smooth, typical coagulum. Microscopic examination of the original culture, and the milk inoculated with the original culture, showed Bulgarian bacilli in pure culture.

The Fairchild lactic bacillary tablets. Four specimens were examined. The bacilli were not in so viable a condition as in the liquid culture. They worked more slowly and a few other bacteria got in, no doubt owing to lodgment on the tablets. Four tablets (not crushed) did not curdle sterile milk after forty-eight hours. In litmus-milk only slight acidity was developed after forty-eight hours. Microscopic examination of this litmus-milk, however, showed only Bulgarian bacilli, although relatively few in number.

Fairchild's lactampoules. These showed the same reactions as the Culture of Bacillus Bulgaricus. Milk was promptly coagulated. Acid formation and coagulation in litmus-milk were typical. Microscopic examination showed the bacilli in pure culture.

Fairchild's bacillary milk. One sample was examined. It had the typical taste, consistency, etc., produced by Bulgarian bacilli in milk. Microscopic examination showed Bulgarian bacilli in pure culture, and inoculation of sterile milk produced typical coagulum, taste and appearance.

2. Preparation of Hynson, Westcott & Co., Bulgara Tablets.

Five original packages of these tablets were examined. The tablets contained pure cultures of Bulgarian bacilli as shown by microscopic examination. In litmus-milk typical curd and acid reactions were produced. Inoculations into sterile milk produced typical coagulum, with very little whey and characteristic taste and appearance. The action was somewhat slower, however, than is produced by liquid cultures. All five samples acted exactly alike.

3. Massolin, prepared by Lederle Laboratories and marketed by Schieffelin & Co.

Three samples of Massolin were examined. They contained pure cultures of Bulgarian bacilli in liquid form. The action was very prompt, more so than any of the other samples of commercial articles examined. Litmus-milk curdled and was acidified in typical fashion. Microscopic examination showed the bacilli to be in pure culture.

Explanation: Typical coagulum produced by Bulgarian bacilli should be smooth, with little or no whey. In litmus-milk the litmus is decolorized, excepting a ring at the top, which is intensely red. Most races produce practically no whey, although certain races produce some. There should never be much whey.

This report shows that while the market-supply—at least that examined in 1909—was highly contaminated, the products described in New and Nonofficial Remedies without exception contain only the *Bacillus bulgaricus*. Further, while all products containing living bacteria are bound to deteriorate, the preparations examined were in viable condition, though, as was to be expected, liquid cultures were more active than the tablet preparations.

In this connection it should be pointed out that besides placing an expiring date on each package, the manufacturers of these products are making every effort to insure the dispensing of reliable products when they are ordered by physicians. These manufacturers have urged pharmacists to keep the lactic acid preparations in ice-boxes or refrigerators, to purchase only a limited supply and in other ways to give special attention to their dispensing as directly as possible from the laboratories of the manufacturers. Physicians should examine the date on the label to be sure the preparation is not too old.

## WHAT'S THE MATTER WITH ILLINOIS?

The *Illinois Medical Journal* has come tumbling down the ladder of progress and joined the ranks of the obstructionists. The number of advertising pages have increased accordingly. But what will the 5,000 members, the large majority of whom, we are convinced, stand for the principle that the State Association and its publications shall uphold the standards of organized medicine, including the rules of the Council on Pharmacy and Chemistry governing advertisements, think of the backward step which their journal has forced them into?

Perhaps there is no more pitiable spectacle in the battle of life than lowering your standard and acknowledging defeat after exhausting all your resources in maintaining a principle. There is no disgrace attached to the conclusion of an issue honestly fought, but when a leader deliberately surrenders his people to the opposing forces while still well armed and eager for battle, he is guilty of a treasonable act and ought to be dealt with accordingly. The *Illinois Medical Journal* until very recently stood for the principles of our organization and its pages were free from objectionable advertisements. With the change in management (it has no editor) comes a disgraceful acknowledgment that it will accept and publish advertisements of articles irrespective of the findings of the Council on Pharmacy and Chemistry concerning the honesty and reliability of those articles. Will the Illinois State Medical Association permit its journal to be prostituted in this disgraceful manner after fighting for years to be consistent, respectable and ethical?—*The Journal of the Missouri State Medical Association, November, 1913.*

## SANATOGEN

### A Restatement of the Case Against This Product

The case against Sanatogen has been pretty plainly given at different times in The Journal,[1] but the sale of the stuff goes on—thanks to the power of advertising. One criticism that has been made of this patent medicine is the exorbitant price charged for it. This objection, although but an incidental one, is the one that apparently appeals to the layman more strongly than the much more serious criticism, fraud in exploitation. You arrest the attention of the average man when you appeal to his purse; he resents paying an exorbitant price for anything. This probably accounts for the fact that this particular criticism has apparently hurt the sale of Sanatogen to a greater degree than the more serious objections made to the preparation. This also accounts, doubtless, for the fact that the attempts to answer The Journal's criticisms, by those who are selling Sanatogen, have been largely devoted to the one point—its outrageously high price.

The fundamental objection to Sanatogen is not its high price, but the attempt to ascribe to a mixture of casein and glycerophosphates powers not possessed by these ingredients—in other words, the misleading and fraudulent claims made for it. Even if it were sold at cost price, the stuff, as at present advertised, would still be a fraud. The nub of the whole matter is: The claims made for Sanatogen are unwarranted, misleading and fraudulent.

#### SOME FRAUDULENT CLAIMS

The constituents of Sanatogen are casein and sodium glycerophosphate. These two very ordinary substances possess, so the Sanatogen people would have us believe, peculiar properties when they are brought together in chemical combination. Sanatogen, they claim, *is* a chemical combination of these constituents. The claim may be a good "selling-point," but it cannot be, and is not, seriously taken by chemists. But even supposing, for the sake of argument, that sodium glycerophosphate and casein could be combined, there is not a scintilla of evidence to show that such a combination could survive the destructive influence of digestion and be absorbed. Whether Sanatogen is a chemical combination of casein and sodium glycerophosphate or a mere mechanical mixture of these two substances is really immaterial. In either case, it would be separated into its constituent parts by the digestive juices and would have the properties of sodium glycerophosphate and casein, and nothing more.

Remembering this, let us examine once more some of the claims made for this patent medicine:

> "Sanatogen is a nerve and tissue food for which the brain, spinal cord and the nerves have a special predilection."
>
> ". . . practically identical with the main ingredient of nerve and muscle cells. . . ."
>
> "Sanatogen stands pre-eminent in its power to feed the nerve centers, to promote healthy digestion, to give strength and endurance to the entire system."
>
> ". . . food for tired nerves. . . ."
>
> ". . . a rational, scientific nerve-food."

To the physiologist, the term "nerve-food" is an absurdity. The processes of digestion reduce the albuminous substances (proteins, such as casein) of the food to simpler forms. This is true no matter what may be their source. Whether the proteins are derived from the gluten of wheat, the casein of milk or the albumin of egg, one will "feed the nerves" just as well as the other. And Sanatogen "feeds the nerves" no more than, in fact not as much as, do bread and meat and eggs. Of course, the casein in Sanatogen has food-value, but so has ordinary casein—cottage cheese, "pot cheese," or the German *schmierkäse*, for instance—and it is both false and fraudulent to claim for the casein in Sanatogen any greater nutritive value than that possessed by the casein in ordinary milk. To pretend that there are wonderful properties in the protein of Sanatogen when just as good protein can be purchased (for much less money) from the milkman, is to perpetrate a fraud on the purchaser. Here are some more claims:

> ". . . marvelous revitalizer of nerve health."
>
> ". . . Sanatogen has positive reconstructive force in neurasthenia."
>
> "If You Need New Strength and Vitality You should at once get acquainted with Sanatogen."

Strangely like the "lost manhood" advertisements, this last. And this, also:

> ". . . has brought new strength, new vitality and new relish of life to thousands upon thousands who suffered from starved nerves. . . ."
>
> "Countless people . . . have regained fresh health and vigor through the vitalizing and invigorating effects of Sanatogen."

Of course Sanatogen is not sold as a "consumption cure." No such crude claims as these emanate from the skilled advertising agents employed by the Sanatogen people. If they did they could not get space in high-grade magazines! As a preventive of consumption, however, we find:

> "Sanatogen . . . creates new tissue and nerve capital . . . This nerve capital will . . . save the individual from attacks of acute disease. Against tuberculosis it is an excellent investment."

Also, it is a pick-me-up! Thus:

> "Sanatogen promises to pick you up when run down—*it does so.*"

Most people are under the necessity of working for a living. If we are to believe the Sanatogen advertisements, it seems remarkable that the human race has managed to jog along for so many centuries without this product, for we read:

> "It is practically indispensable to all who are unable to take prolonged rest. . . ."

Naturally we do not expect to find the coarse, "free-to-you-my-sister" type of claims in Sanatogen advertisements. Nevertheless:

> "Women . . . find in Sanatogen a genuine sustaining agent."

Finally, we would respectfully direct the attention of those gentlemen of the medical profession who have so far forgotten the dignity of their calling as to give fulsome puffs for this casein-glycerophosphate product to the following claims and ask whether they really subscribe to them:

> ". . . it revivifies the nerves, promoting sleep and helping digestion. . . ."
>
> ". . . it builds up the blood, creating new strength and the power to do and accomplish."
>
> ". . . Sanatogen is a *natural*, healthful food and tonic. . ."
>
> ". . . a health and strength giving food and tonic composed of those very elements which make cell and tissue grow."
>
> "Blood and tissues alike hunger for Sanatogen as their concentrated nourishment."
>
> "Sanatogen is the one food tonic that commands your absolute confidence."

How many intelligent physicians really believe that there is the slightest basis of fact for the claims we have quoted? Yet it is by means of these claims that Sanatogen is being foisted on a public that looks to the medical profession for enlightenment and truth. And every quotation in this article is taken from advertising matter issued during the current year, 1913!

In closing, let us reiterate: The objections to Sanatogen are primarily the objection to any fraud. It is being sold under unscientific, misleading and fraudulent claims; moreover, although this is of less importance, the purchaser pays an extraordinary price for a most ordinary product. We believe the time will come when even the artificial stimulus of vast advertising appropriations will be insufficient to overcome the inertia inherent in a product of small merit. When that time comes, Sanatogen will die a natural death. In the meantime, its exploiters are reaping a golden harvest, of which no small part is being divided among publishers, medical and otherwise. And the credulous among the sick and suffering pay the bills!

---

[1] The present article and previous ones on this subject are reprinted in a pamphlet entitled "Sanatogen," price 4 cents.

## Miscellany

**Preservation of Eggs by Refrigeration in Sterile Air.**—M. F. Lescardé at the Third International Congress of Refrigeration described a method of preserving eggs by refrigeration in sterile air. The eggs are placed on end in horizontal fillers made of pasteboard and wood; then these fillers are put into tin cases which can be hermetically sealed, each case having a capacity of six fillers containing 160 eggs. The covers of the filled cases are then soldered, and the cases are deposited in an autoclave (digester) which contains twelve cases of 960 eggs each. A vacuum is then made in the autoclave, and a duly proportioned mixture of two gases, carbon dioxid and nitrogen, is injected. This process is very simple because carbon dioxid and nitrogen, in the form of compressed or liquefied gases, are on the market now, so that the manipulation of a few cocks, and the reading of a gauge suffice to produce the proper mixture. The process in the autoclave having been completed, the cases are taken out, hermetically sealed, and stored in cold storage rooms, at a temperature varying between 1 and 2 C. The chief advantages accruing from the preservation of eggs in sterile air are the following: (1) Waste, of such importance in ordinary cold storage, is completely eliminated. (2) The eggs retain a perfectly "fresh" flavor, and consequently they remain excellent for table use even after ten months' storage; they also retain their full weight, because no evaporation is possible in the tin cases. (3) After their removal from the cold storage rooms the eggs remain in perfect condition for a long time, and can be shipped long distances without deterioration; this constitutes a signal superiority over the ordinary cold storage eggs, which deteriorate rapidly after having been taken out of cold storage. The reason for this is simple: the antiseptic air which surrounds them for several months, together with the cold, absolutely destroy all bacteria which may be on the shell of the egg, or in its substance. Deterioration cannot set in except by reinfection, which is produced only by exposure to the air for several weeks. By reason of the above-mentioned advantages, eggs preserved in sterile air find a ready market, and command much higher prices in winter than ordinary cold storage eggs, or even the so-called "fresh" imported eggs. The cost of treatment and preservation, amount to 15 francs per thousand.

**The Decidua Has an Internal Secretion.**—Gentili gives a detailed description in the *Ann. di Ostet. e Ginecol.*, 1913, xxxv, 257, of experiments with aqueous extracts of the decidua of cows, dogs and human beings. These extracts proved very toxic when injected in small doses into the circulation of rabbits. The extract of rabbit and guinea-pig decidua is also toxic for their own species, though in larger doses. The toxic phenomena are similar to those caused by injection of extracts of the glands which have an internal secretion; but contrary to the action of these extracts, the decidua extract is more toxic for different species. The post-mortem picture in animals dying from the effect of the injection of decidua extract is similar to that of animals dying from fatal doses of extracts of other organs having internal secretion. There was thrombosis of the pulmonary veins, showing the presence of some substance that favors coagulation of the blood within the body. This substance can be neutralized by blood-serum from the same species of animal from which the decidua was taken. In cows, particularly, the greater toxicity was in the early stages of pregnancy. Aside from its toxic effects, decidua extract always has the property of causing a marked fall in blood-pressure. It lessens the force of the systolic wave and produces disturbance in the cardiac and respiratory rhythm. Similar but less pronounced phenomena are produced by extracts of the corpus luteum. It is evident from these results that the conjecture that the decidua has an internal secretion is no longer merely a logical supposition, but has been demonstrated by experiments to be a fact.

## Correspondence

### Federal Regulation of the Practice of Medicine

*To the Editor:*—I have read your comments on the Reilly bill (THE JOURNAL, Oct. 25, 1913, p. 1557) to the effect that the Reilly bill is "an impossible proposal," by reason of the fact that in the United States "the regulation of the practice of medicine comes under the police power of the state legislatures and not under that of Congress," and further that "the consideration of any measure by Congress providing for the control of the practice in the states by any federal board is simply a waste of time, as any such measure, even if adopted, would be declared unconstitutional as soon as it came into court." If your views correctly state the powers of Congress, this bill should and will be killed in the committee in charge, notwithstanding the fact that "in every other civilized nation such national control is in effect" and the desirability of such a control is generally recognized in the United States. For myself and other readers of THE JOURNAL to whom I have spoken, none of whom are deeply versed in constitutional law, but who are possessed of an abiding faith in the powers of Congress to legislate for the general welfare of the citizens of the whole United States even to the extent of guarding the health and life of every citizen of the land; and who are imbued with a belief that the preamble of the Constitution of the United States did not in general terms overstate the powers conferred on Congress by the Constitution at the time of its adoption, and with a belief that the powers of Congress were enlarged, and not weakened, by the subsequent amendments, it is difficult to accept the view that Congress has not the power to provide for the common defense and general welfare of all the people in like manner as the states may do for all the people within their borders in the exercise of the so-called police power of the state. Although Congress has not in the past supplemented the powers of the state in all cases with her general power to promote the general welfare of citizens of the United States in the matter of guarding their lives and health, such omissions do not justify the inference that Congress is void of the power to do so. Congress has recently exercised this latent power on more than one occasion. Congress possesses all the powers conferred by the eighth section of the United States Constitution, and, in addition to the powers mentioned in Section 8 of the federal Constitution, Congress may do anything that is not prohibited by the Constitution. These latent powers of Congress have supplemented the police powers of the state in the passage of the federal Food and Drugs Act, generalizing the Pure Food and Drugs Law of the state of Indiana passed in the exercise of the police power of that state a few years previously to the federal law, and the Supreme Court has not annulled the federal law.

Congress has within the last few months passed a national income-tax law supplemental to the income-tax laws of many of the states, and no good lawyer will gainsay the constitutional right of Congress to do so. Neither do I find any decisions by any court of last resort denying Congress the latent power to provide for the general welfare even to safeguarding the lives and health of the citizens of the United States by a congressional regulation of the practice of medicine. Will you not in some future editorial assist your readers to a clearer understanding of the constitutionality of the Reilly bill by citing a few Supreme Court decisions showing that Congress has not the power to promote the general welfare of the people of the United States even to the federal regulation of the practice of medicine? So long as that regulation applies to all parts of the union equally, let your readers have "thus sayeth the law" and be convinced.

M. M. CLAPPER, M.D., Hartford City, Ind.

COMMENT.—The reference of our correspondent to the new income-tax law is the best possible illustration of the limitations of federal power. It will be remembered that Congress, a number of years ago, did pass an income-tax law, which was promptly decided by the United States Supreme Court to be unconstitutional. An amendment to the Constitution was then prepared and submitted to the states. As soon as the necessary number of states had ratified it, Congress at once passed an income-tax measure. If the Reilly bill or any similar measure should become a law, the Supreme Court would without doubt declare it unconstitutional. An amendment to the Constitution similar to the income-tax amendment would then be necessary to make such a law valid.

Taking up now the question raised by our correspondent, the expression "public welfare" embraces a variety of interests. It may refer to primary social interests of safety, order and morals; to economic interests, or to political interests. The federal government, through its constitutional authorization, has delegated to it, in large part, chiefly the third class of interests, while the first two are reserved to the several states or to the people. As a result, it would appear from the best authorities that there can be no federal regulation of the practice of medicine whereby a person may, under a federal license, be authorized to practice in any given state, and contrary to the laws thereof. That is to say, that each state only may determine who is to practice medicine within its jurisdiction, and that Congress has no power to legislate to that end. (Freund, Police Power, Paragraph 9. Stimpson, The American Constitutions, Chapters 3, 10, pp. 60, 106).

The profession of the physician, whose relations to life and health are of the most intimate character, and thereby closely associated with "safety, order and morals," would clearly seem to fall within the first group, that is, the "primary social interests." It is almost entirely because of this intimate relationship, whereby the ignorant and credulous may be imposed on by empiricists and charlatans, that the government is authorized to enact certain conditions for the regulation of the medical profession. The right to impose such regulations is derived from the "power of police," or power to prohibit and prevent the perpetration and promulgation of any act *per se* fraudulent. "Police power" is inherent in all governments or sovereignties. That is, the right and authority to issue police regulations for the furtherance of the public safety, order and morals or for the social interests, is a consequence of the establishment of government. But, under the Constitution of the United States, the federal government has only such powers as are either expressly or impliedly vested in it. All other powers are reserved to the several states or to the people. Among such reserved powers are the powers of police within the jurisdiction of each of the several states, and included therein is the right to regulate the practice of medicine within the confines of each of the states. (Freund, Police Power, Paragraphs 10, 64, 65, 68, 85. *Dent v. West Virginia*, 129 U. S. 114; *Hawker v. New York*, 170 U. S. 189; *Jacobson v. Massachusetts*, 197 U. S. 11; *State v. Hathaway*, 115 Mo. 36.)

A state regulates its domestic commerce, contracts and the transmission of estates, real and personal, and acts on all internal matters which relate to its moral and political welfare. Over these subjects the federal government has no power. The "police power," which is exclusively in the states, is alone competent to preserve the public peace, health and morals. Nor can this power be taken from the states, either wholly or in part, and exercised under legislation of Congress.

The precise question as to the constitutionality of a federal enactment regulating the practice of medicine has not, so far, been decided by the United States Supreme Court because no federal law providing for such regulation has ever been enacted; but an examination of the several cases, cited herewith, would seem to show that all legislation regulating the practice of medicine is but an exercise of that "police power" vested solely in each of the several states to control the "primary social interests" as to health, morals and safety, and further, that from the very institution of our form of government, state and federal, all such affairs as the regulation of the liquor traffic, the regulation of the practice of medicine, and in fact any matter involving the intimate relations of daily life as between man and man, were specifically vested in the states. Hence it would clearly seem to follow under the rule that a court must follow the law as heretofore decided in prior cases, that the validity of such a measure could hardly be decided otherwise than negatively. (*Martin v. Hunter's Lessee*, 1 Wheaton 304; License Cases, 5 Howard 4; United States v. DeWitt, 9 Wallace 41; *Barbier v. Connolly*, 113 U. S. 27; *People v. Compagnie Générale*, 2 Sup. Ct. Rep. 87; *Mugler v. Kansas*, 123 U. S. 623; *Gundling v. Chicago*, 177 U. S. 183; *Compagnie Française v. Louisiana*, 186 U. S. 380; *Jacobson v. Massachusetts*, 197 U. S. 11; *Williams v. Arkansas*, 217 U. S. 546).

No power has been conferred on the federal government by the Constitution of the United States whereby the government may establish mere police regulations within the jurisdiction of any state. And the federal government can claim no power not granted by the Constitution; hence federal authority is limited to a simple prohibition on the states as against any invasion of the sphere of national sovereignty.

Thus, it would seem to be well settled that the police powers of the states extend to the regulation of those callings which closely concern the public health. And further, it would seem clear that legislation which simply defines the qualifications, and provides for the licensure, of one who attempts to practice medicine within the jurisdiction of any given state is something confessedly belonging to the domain of the police power as vested in that state. Hence it is that no power can be found vested in Congress authorizing a federal regulation of the practice of medicine within the confines of any one or all of the several states. This view is evidently held by the United States Supreme Court in all the cases involving the state control of the practice of medicine which have come before it. (*Dent v. West Virginia*, 129 U. S. 114; *Hawker v. New York*, 170 U. S. 189; *Reetz v. Michigan*, 188 U. S. 505; *Watson v. Maryland*, 30 Sup. Ct. Rep. 644).

## The Regeneration of the Blood After Splenectomy

*To the Editor:*—The editorial on this subject (THE JOURNAL, Nov. 15, 1913, p. 1816) gives such an incorrect idea of the present state of our knowledge concerning this subject that I feel compelled to call attention to certain discrepancies in the data on which the editorial is based. An extensive study of the changes in the blood following splenectomy in the normal dog, carried out under my direction during the past two years (Pearce, R. M.: The Relation of the Spleen to Blood Destruction and Regeneration and to Hemolytic Jaundice, Papers I-VII, *Jour. Exper. Med.*, 1912, xvi, 363, 375, 758, 769, 780; 1913, xviii, 487, 494; an eighth paper is now in press [*Jour. Exper. Med.*, December, 1913]) has demonstrated conclusively that the spleenless animal always develops an anemia which is progressive for several weeks, usually reaching its period of greatest severity after from three to six weeks and then gradually improving with a return to normal after from three to five months. This is a constant occurrence, demonstrated again and again, in many animals. In Vogel's work (from Asher's laboratory), which is the basis of the editorial opinion, a diet with high iron content was commenced eighteen days after splenectomy. As the condition of the blood improved, it was assumed that this improvement was due to the high iron content of the diet. This conclusion rests on a single experiment on a splenectomized dog with a normal dog as control. There is no control of the experiment by a study for a long period of the blood-picture in a splenectomized animal on an ordinary or low iron diet. The administration of a diet rich in iron was begun, not immediately after splenectomy, but after eighteen days, when, according to observations, regeneration of the blood usually begins. The question naturally arises, Was the improvement in Vogel's single experiment due to diet or to the regeneration naturally occurring at this time? The theory that one function of the spleen is to regulate the iron metabolism is most plausible, but it should have more definite basis than that offered by a single experiment. In our own work on iron metabolism in the splenectomized dog, on low and high iron diet, though four splenectomized animals have thus far been used, we have on account of the discordant results of chemical analysis reached no definite conclusions.

On the basis of Banti's theory (that in certain forms of splenomegaly the accompanying anemia is due to a hemolysin of splenic origin) splenectomy, in that improvement follows the procedure, may have some justification; but in pernicious anemia the justification is not so clear and the results thus far reported are by no means uniformly favorable. If it is done as a last resort and a forlorn hope it may perhaps be countenanced, but it should be definitely understood that the procedure is not in accord with such experimental evidence as we have at hand. The problems concerning the spleen in its relation to blood destruction and regeneration are exceedingly complex, and the experimental and clinical evidence often paradoxical; but until more definite knowledge is at hand splenectomy in anemia, not accompanied by splenomegaly as in the Banti type, should not be urged as a procedure having a definite scientific basis.

R. M. Pearce, M.D., Philadelphia.

[Comment.—We are glad to print the foregoing communication from Professor Pearce and to call attention in this way to his researches on the relation of the spleen to the blood. The question of the relation of the spleen to iron metabolism is, it must be frankly admitted, still *sub judice.* With respect to the final contention in the foregoing communication we believe that we were quite as cautious in drawing any permanent conclusions as Professor Pearce has been. Our object was essentially to give prominence to a suggestion which is not entirely devoid of an experimental background. The limitations of our knowledge in this field were plainly referred to.—Ed.]

### "Burnam's Test" for Formaldehyd: a Question of Priority

*To the Editor:*—Hugh Cabot and O. R. T. L'Esperance in an article entitled "The Excretion of Formaldehyd by the Kidneys of Patients Taking Hexamethylenamin, a Study of Burnam's Test" (*Boston Med. and Surg. Jour.*, Oct. 24, 1912, p. 577), and later B. F. Jeness in an article entitled "Burnam's Test for Formaldehyd in the Urine" (The Journal, March 1, 1913, p. 662) described in detail a method for determining small quantities of formaldehyd in the urine, calling this method, both in the title and in the text, "Burnam's test." This test consists in the use of dilute solutions of phenylhydrazin hydrochlorid, sodium nitroprussid and sodium hydroxid. It is a delicate color reaction, for all practical purposes specific for formaldehyd and very sensitive, revealing the presence of minute quantities of formaldehyd, even in albuminous fluids, such as milk, nephritic urine, etc.

This so-called "Burnam's test" was discovered by Rimini (*Ann. di Farmacol.*, 1898, p. 97), and has been in use extensively ever since as "Rimini's test." I have used it for years in my formaldehyd work (see *Tr. Chicago Path. Soc.*, 1912), my attention having first been called to it in a paper by Fenton (*Tr. Chem. Soc.*, 1907, xci, 693), who speaks of "Rimini's test" as one of the most reliable methods for detecting small quantities of formaldehyd. In looking the matter up, I find "Rimini's test" given as a standard method in several lexicons and encyclopedias of practical chemistry.

Why deprive the discoverer of this important method of the distinction of having his name attached to it? It is "Rimini's test" and not "Burnam's test," and should be so named by all who use it—including Burnam and his coworkers.

A. C. Croftan, M.D., Chicago.

## *Queries and Minor Notes*

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

### FACIAL SPASM

*To the Editor:*—What is the probable cause of involuntary unilateral twitching (spasm) of the pyramidalis nasi muscle? Spasms come on frequently during the day, last five minutes or so and stop. *Embarrassment* results from the grimacing. There is no discoverable cause in ear, nose or throat. What portion of the facial nerve is probably affected, and what treatment could you suggest?

Q., Walla Walla, Wash.

Answer.—The etiology of facial spasm is still an obscure chapter in medicine. Owing first to the intimate relationships existing between psychic activity and facial expression and, secondly, because of the many connections between the facial nerve and numerous sensory nerves, we recognize two general causes, psychic and reflex, for the production of involuntary facial twitching. To the psychic variety belongs the large group of facial tics, called also tic convulsif, conditions having a psychogenic basis and consequently *curable only* by psychic means. Meige and Feindel have published an interesting book (Tics and Their Treatment, translated by S. A. K. Wilson; New York, William Wood & Co., 1907, $3), the classic on this subject, which contains not only the etiology and the varied symptomatology of tic convulsif, but also a detailed treatment of this type of facial unrest. With reference to reflex facial spasm, every organ in contiguity to the face and supplied by the trigeminus or other cranial nerve, and even organs remote from the facial territory, must be carefully examined and any existing pathologic condition remedied. Oppenheim, for instance, has seen the disappearance of spasm in the pyramidalis nasi by removal of enlarged tonsils; others have had the same result by correcting uterine displacements and relieving genital disorders. Rarely facial spasm is caused by direct compression of the facial nerve by either tumor or aneurysm, in which event the underlying condition must be treated. In a few cases localized facial spasm is produced directly by the occupation which the patient follows, as for instance the spasm in orbicularis and nasal muscles occurring in watchmakers. In the majority of cases, however, a definite anatomic basis is not demonstrable. Last but not least, there is a slight twitching, more felt than seen, in the orbicularis and nasal muscles which results from states of fatigue and nerve-strain and is frankly neurasthenic in character. In these cases the treatment of neurasthenia will be indicated. It is impossible to give definite directions for the treatment of a symptom having so many possible causes. In a general way it will be necessary to decide whether the case is one of tic or true spasm. Tic is treated by psychotherapy, while the facial spasm must be treated according to the nature of the lesion, depending on the origin and pathology of the symptom—from the performance of a brain operation to the touching up of the nasal mucosa with silver nitrate.

### ARTICLES ON DYNAMIC ILEUS

*To the Editor:*—Please furnish me with all available literature on the subject of dynamic ileus.

Edwin D. Watkins, M.D., Memphis, Tenn.

Answer.—The following list includes the most recent articles on this subject:

Vaccari, L.: Postoperative Paresis of the Intestines, *Policlinico*, Jan. 28, 1912.
Dieffenbach, W. H.: Electric Treatment of Intestinal Obstruction and Postoperative Paralysis of the Bowel, The Journal, April 1, 1911, p. 958.
Illoway, H.: Hysteric Paralysis of Intestines, *Arch. f. Verdauungskr.*, 1912, No. 3; Hysteric Paralysis of Somewhat Rare Form, *Arch. Diagnosis*, October, 1911.
McElhaney, C. W.: Ileus Paralyticus Relieved by Operation, *Med. Fortnightly*, March 10, 1911.

### THE VALUE OF ECHINACEA

*To the Editor:*—Is there any great value in echinacea, and if so in what does it consist? I find a good many physicians using it who seem to think that it possesses value as preventing the formation of pus, and in perhaps getting rid of pus after it has formed. In the many cases which I have seen in which it was used, I have been unable to satisfy myself that any effect whatever was produced, and I have looked on it, therefore, as entirely worthless. Some physicians give it by the stomach, and some hypodermically, the latter claiming great increase of virtue when it is thus given.

Surgeon.

Answer.—Echinacea has been claimed to be a "specific" for rattlesnake bite, syphilis, typhoid fever, malaria, diphtheria and hydrophobia. Later enthusiasts have credited it with equally certain curative effects in tuberculosis, tetanus and exophthalmic goiter, and with power of retarding the development of cancer. On the basis of the available evidence the Council on Pharmacy and Chemistry decided that echinacwas not worthy of recognition as a drug of probable value. Accordingly it voted not to describe the drug in New and Nonofficial Remedies (THE JOURNAL, Nov. 27, 1909, p. 1836).

So far as can be learned no reliable evidence for the claims made for this drug has been presented since the Council decided that the available evidence did not entitle it to a place in New and Nonofficial Remedies.

### DOES SMALL-POX PROTECT AGAINST BOVINE VACCINATION?

*To the Editor:*—In THE JOURNAL, Oct. 25, 1913, p. 1556, in answer to this question of Dr. R. P. Stark, you answer, "Yes." I do not know on what data you found your answer, as opportunities to try the experiment must seldom present themselves. No physician would be apt to urge vaccination on a person who has had small-pox; but I once had an opportunity to try it, and the result was quite a surprise both to the patient and to myself. In 1880 I was a vaccinator of the board of health during an epidemic in this city. In the course of my wanderings among the dwellers in the tenement-houses, offering them vaccination, I came across a woman of about 50, deeply pitted from an attack of variola sustained while a child in Ireland. In joke, I offered to vaccinate her. To my surprise she consented. I explained to her that it might take, and if so, would probably make her quite sick, and assured her that as a prophylactic she had no need of it, as she was already better protected against another attack than any vaccination I could give her But she was very anxious to try the experiment and so I vaccinated her. After about a week she developed as fine a primary as I have ever seen, with considerable malaise, fever, etc., which ran the usual course.

E. HOCHHEIMER, M.D., New York.

ANSWER.—This case is, of course, somewhat exceptional, but other instances of a like nature have been reported. That the development of vaccinia is prevented by the presence of an active small-pox is shown by the fact that vaccination does not take when performed before or during the primary fever of small-pox. It is not impossible that an immunity should disappear after a long period of time.

### OPERATION FOR LACERATED CERVIX—TREATMENT IN PARALYSIS OF LEGS AFTER POLIOMYELITIS

*To the Editor:*—1. What is the approved method of dealing with a lacerated cervix at time of delivery?

2. Please name other measures of benefit besides persistent massage and hygiene for paralysis of both legs in a young child following poliomyelitis.

H. T.

ANSWER.—1. The operation should be postponed to the latter part of the puerperium unless hemorrhage is serious, in which case immediate suture should be resorted to.

2. Endeavor should be made to induce the child to use vigorously any muscles which remain unparalyzed. Sometimes the slowly interrupted galvanic current will excite contractions in the larger muscles, and if this is the case it should be used for a few minutes twice a day. Any tendency to deformity should be opposed by appropriate apparatus. Foot-drop is most apt to occur, and can usually be prevented by a simple Taylor club-foot brace. If severe contractions develop rapidly, conservative tenotomy and redressment may be required. After about two years of conservative treatment, the case will be ready for radical operation according to the indications, tendon transplantation if possible, joint fixation if necessary. The object, of course, is to enable the patient to walk without apparatus, although this object cannot always be attained.

### ARTICLES ON ABDERHALDEN'S SERODIAGNOSIS

*To the Editor:*—Please describe the technic for the Abderhalden reaction especially as applied to organic diseases. I want to try it out with the different forms of epilepsy and insanity.

H. M. FRANCISCO, M.D., Skillman, N. J.

ANSWER.—The Abderhalden test as applied to the diseases mentioned is performed with a technic based on that for pregnancy. THE JOURNAL has published the following articles on the subject:

The Present Status of Abderhalden's Serodiagnosis, editorial, THE JOURNAL, Aug. 16, 1913, p. 493.
Fauser, A.: Serodiagnosis by Abderhalden's Technic, Deutsch. med. Wchnschr., Feb. 13, 1913; abstr., THE JOURNAL, March 22, 1913, p. 949.
Judd, C. W.: The Serum Diagnosis of Pregnancy, THE JOURNAL, June 21, 1913, p. 1947.
Schwarz, Henry: Serodiagnosis of Pregnancy, THE JOURNAL, Aug. 16, 1913, p. 484.
Abderhalden's Test in Cancer, editorial, THE JOURNAL, Oct. 18, 1913, p. 1461.
The Blood Test for Pregnancy, THE JOURNAL, Dec. 7, 1912, p. 2073.
Technic of Abderhalden's Serodiagnosis for Dementia Praecox, Queries and Minor Notes, THE JOURNAL, May 31, 1913, p. 1727.

# *Medical Education and State Boards of Registration*

## COMING EXAMINATIONS

ALABAMA: Montgomery, Jan. 13. Chairman, Dr. W. H. Sanders, Montgomery.
ARIZONA: Phoenix, January 3. Sec., Dr. John Wix Thomas, 200 National Bank of Arizona Bldg., Phoenix.
COLORADO: State Capitol, Denver, January 6. Sec., Dr. David A. Strickler, 612 Empire Bldg., Denver.
DELAWARE: State Society and Homeopathic, Dover and Wilmington, Dec. 9-11. Secretary of the Medical Council, Dr. Henry W. Briggs, 1026 Jackson St., Wilmington.
ILLINOIS: The Coliseum Annex, Wabash Ave. and 16th St., Chicago, Jan. 14-16. Acting Sec., Amos Sawyer, Springfield.
INDIANA: Room 56 State House, Indianapolis, Jan. 13-15. Sec., Dr. Wm. T. Gott, 56 State House, Indianapolis.
IOWA: The Capitol Bldg., Des Moines, January 6-8. Sec., Dr. Guilford H. Sumner, Capitol Bldg., Des Moines.
KENTUCKY: Armory, Louisville, Dec. 11-13. Sec., Dr. J. N. McCormack, Bowling Green.
MARYLAND: Regular, 1211 Cathedral St., Baltimore, Dec. 9. Sec., Dr. J. McP. Scott, Hagerstown; Homeo., St. Luke's Hospital, Baltimore, Dec. 15-16. Sec., Dr. O. N. Duvall, 1817 N. Fulton Ave., Baltimore.
MINNESOTA: State University, Minneapolis, January 6-9. Sec., Dr. Thos. S. McDavitt, 814 Lowry Bldg., St. Paul.
NEW HAMPSHIRE: State House, Concord, January 6-7. Regent, Mr. H. C. Morrison, State House, Concord.
NEW MEXICO: Santa Fe, Jan. 12. Sec., Dr. W. E. Kaser, East Las Vegas.
NORTH DAKOTA: Grand Forks, January 6. Sec., Dr. G. M. Williamson, Grand Forks.
OHIO: Columbus, Dec. 9-11. Sec., Dr. Geo. H. Matson, State House.
OKLAHOMA: Oklahoma City, Jan. 13. Sec., Dr. John W. Duke, Guthrie, Okla.
OREGON: Portland, January 6-8. Sec., Dr. L. H. Hamilton, Medical Bldg., Portland.
SOUTH DAKOTA: Capitol Bldg., Pierre, Jan. 13. Sec., Dr. Park B. Jenkins, Waubay.
VERMONT: Montpelier, Jan. 13-15. Sec., Dr. W. Scott Nay, Underhill.
VIRGINIA: Richmond, Dec. 16-19. Sec., Dr. Herbert Old, Norfolk.
WASHINGTON: Spokane, January 6-12. Sec., Dr. F. P. Witter, Traders' Block, Spokane.
WISCONSIN: Madison, Jan. 13. Sec., Dr. John M. Beffel, 3200 Clybourn St., Milwaukee.

## Nebraska August Report

Dr. H. B. Cummins, secretary of the Nebraska State Board of Health, reports the written examination held at Lincoln, August 13-14, 1913. The number of subjects examined in was 8; percentage required to pass, 75. The total number of candidates examined was 16, all of whom passed. Eight candidates have been granted licenses through reciprocity. The following colleges were represented:

PASSED

| College | Year Grad. | Per Cent. |
|---|---|---|
| Bennett Medical College | (1913) | 77.5, 80.4 |
| Chicago College of Medicine and Surgery | (1913) | 79.6 |

## Ohio July and October Reciprocity Reports

Dr. George H. Matson, secretary of the Ohio State Medical Board, reports that at the meetings held July 7 and October 14, 1913, twenty candidates were licensed through reciprocity. The following colleges were represented:

LICENSED THROUGH RECIPROCITY

| College | Year Grad. | Reciprocity with |
|---|---|---|
| Denver and Gross College of Medicine | (1909) | Colorado |
| University of Colorado | (1911) | Colorado |
| George Washington University | (1902) | Dist. Colum. |
| American Medical Missionary Coll., Chicago | (1909) | Michigan |

| | | |
|---|---|---|
| Rush Medical College, Chicago | (1913) | Nebraska |
| University of Illinois ......... (1909) Illinois; | (1912) | Illinois |
| Indiana University | (1908) | Indiana |
| Keokuk Medical College | (1904) | Iowa |
| University of Iowa, College of Medicine | (1913) | Iowa |
| University of Louisville..... (1912) Kentucky; | (1912) | W. Virginia |
| University of Michigan | (1912) | Michigan |
| St. Louis University | (1905) | Missouri |
| Washington University, St. Louis | (1912) | Illinois |
| Long Island College Hospital, N. Y. | (1899) | New York |
| University of Buffalo | (1897) | New York |
| Cleveland Homeopathic Medical College | (1909) | New York |
| Ohio Wesleyan University | (1911) | Illinois |
| Western Pennsylvania Medical College | (1908) | Penna. |

One candidate, a graduate of the University of Naples, 1908, was examined, and passed with a grade of 86.9.

## Arizona October Report

Dr. John Wix Thomas, secretary of the State Board of Medical Examiners of Arizona, reports the written and practical examination held at Phoenix, Oct. 7-8, 1913. The number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 13, of whom 7 passed and 6 failed, including 3 osteopaths. Eight osteopaths were licensed through exemption. The following colleges were represented:

PASSED

| College | Year Grad. | Per Cent. |
|---|---|---|
| University of Colorado | (1912) | 77.7 |
| Bennett Medical College | (1912) | 80.4 |
| Chicago Medical College | (1901) | 84.1 |
| Indiana University | (1912) | 80.6 |
| University of Louisville | (1909) | 81.1 |
| College of Physicians and Surgeons, Baltimore | (1890) | 75.4 |
| National Medical College, Mexico City | (1896) | 74.7* |

* Credit allowed for years of practice.

FAILED

| | | |
|---|---|---|
| Atlanta School of Medicine | (1907) | 63.1 |
| John A. Creighton Medical College | (1905) | 70.6 |
| Louisville Medical College | (1893) | 65.2 |

## Colorado October Report

Dr. D. A. Strickler, secretary of the Colorado State Board of Medical Examiners, reports the written examination held at Denver, Oct. 7, 1913. The number of subjects examined in was 8; total number of questions asked, 80; percentage required to pass, 75. The total number of candidates examined was 10, of whom 9 passed and 1 failed. Twenty-nine candidates were licensed through reciprocity. The following colleges were represented:

PASSED

| College | Year Grad. | Per Cent. |
|---|---|---|
| University of Colorado, (1912) 75.7; 79.7; 89.5; (1913) 75.8; 76.2;; 80.1; 81.2; 83.4. | | |

The following questions were asked:

ANATOMY

1. Explain the bony formation of the elbow joint, naming the bony prominences which can be palpated, with their normal relationship. 2. Discuss the construction of the cranium, naming bones and stating how its anatomical formation tends to lessen the force of external violence. 3. Describe the inguinal canal. 4. Give complete anatomy of the sternomastoid muscle. 5. Define flexion, extension, adduction and rotation; mention muscles with attachments which perform these functions. 6. Draw a chart illustrating the blood-supply of the uterus with comments. 7. Trace the course of the main arterial trunk of the lower extremity from the bifurcation of the aorta to the popliteal space. 8. Describe the portal system of veins. 9. What is the thoracic duct? Give origin and course. 10. What is the fissure of Rolando, its significance, and how may it be located on the cranium?

PHYSIOLOGY

1. Give the function of the liver, and of the bile. 2. Describe the functions of the skin, mucous and serous membranes. 3. What are the characteristics of normal urine? 4. Give functions of pneumogastric nerve. 5. What digestive ferments act upon the starches in food, and how? 6. Describe the gross and minute structure of the heart, veins and arteries, giving the bearing on their physiological functions. 7. Name four reflex centers situated in the lumbar enlargement of the spinal cord, with their functions. 8. What do you understand by metabolism? 9. Describe and give the function of the pancreas. 10. Name five ductless glands and define what you understand by internal secretions.

CHEMISTRY

1. Quantitative test for albumin and test for albumose. 2. What constituents of the blood carry oxygen and carbon dioxid? 3. What are the chief chemical constituents of bile? 4. Formula of calomel, and corrosive sublimate, urea, chloral hydrate, sodium borate. 5. What is the chemical reaction when strychnia sulphate is dissolved in an alkaline solution? 6. Define an acid salt and a ketone. 7. What is the chemical composition of human milk in percentages? 8. Give the method of detecting potassium cyanid in the body. 9. Give the difference between a carbohydrate and a hydrocarbon. 10. Write the reaction which occurs when hydrochloric acid, zinc and water act in the presence of arsenic-bearing tissue.

TOXICOLOGY

1. If you were called to see a case with the following symptoms what would be your diagnosis? Headache, imperfect vision, dilated pupils, difficulty in swallowing, drowsiness, tingling sensation along the muscles, gradual and complete paralysis of extremities, extending finally to the muscles of respiration, and patient dies of apnea. 2. What would be your treatment? 3. Give the symptoms of poisoning by atropin. 4. Give treatment of poisoning by atropin. 5. Give symptoms of poisoning by strychnia. 6. Give treatment of poisoning by strychnia. 7. Give symptoms of poisoning by tartar-emetic. 8. Give treatment of poisoning by tartar-emetic. 9. Give post-mortem appearance of poisoning by tartar-emetic. 10. Define toxicology.

SYMPTOMATOLOGY

1. Describe the Widal reaction and tell its uses. 2. Give the symptoms, physical signs and course of a cas[illegible] pneumonia. 3. What are the symptoms of peptic [illegible] the symptoms and signs of dilatation of the [illegible] the causes of ascites and tell how it may be disc[illegible] a case of pulmonary emphysema. 7. Give the symptoms and signs of acute pleurisy with effusion. 8. Give the causes and symptoms of amyloid disease of the kidneys. 9. Describe a case of hysteria. 10. Give the causes, symptoms and signs of dilatation of the heart.

PATHOLOGY

1. Differentiate between benign and malignant tumors. 2. Describe the forms of malignant tumors. 3. What pathologic changes may result from cerebral hemorrhage? 4. Describe hypertrophic cirrhosis of the liver. 5. What is the pathology associated with atrophic cirrhosis of the liver? 6. Describe gonorrheal arthritis. 7. What is an embolus? State the sources of emboli and the sequelae of embolism. 8. What is ischemic paralysis? 9. What are cysts? 10. Give a general explanation of the pathology of edema.

SURGERY

1. Describe the different types of club-foot. 2. What is the pathology of the most common type of dislocation of the shoulder? 3. Give the symptoms and diagnosis of acute appendicitis. 4. What are the structures which would be divided in an amputation through the middle of the forearm? 5. What part of the tibia is most frequently fractured, and what are the symptoms of fracture in this region? 6. Give the diagnosis and pathology of chronic enlargement of the prostate. 7. What are the symptoms and diagnosis of stone in the urinary bladder? 8. What is Pott's fracture? Describe the symptoms. 9. What are the symptoms of acute suppurative arthritis of the knee-joint? 10. What are the symptoms of Pott's disease?

OBSTETRICS

1. Name possible sources of puerperal hemorrhages and treatment of each. 2. What would lead you to suspect extra-uterine pregnancy? 3. In breech presentation describe the different methods of delivering the aftercoming head. 4. You are called upon to take care of a woman in labor; describe how you would proceed as regards sterilization of yourself. 5. Give symptoms of rupture of the uterus. 6. How may you prevent perineal lacerations? 7. Outline treatment for the prevention of ophthalmia neonatorum. 8. Discuss the preventive treatment of eclampsia. 9. Give treatment of eclampsia. 10. Give the mechanism of L. O. A.

---

**Scope of Preventive Medicine.**—Preventive medicine means more than vaccination against disease, disinfection and sanitation. It means as well the study of heredity and practice of eugenics, subjects which every physician should consider who is anxious to contribute his share to the prevention of disease and improvement of the race.—L. M. Mervin Maus, in *Chicago Med. Recorder*.

Interstitial Gingivitis and Pyorrhea Alveolaris. By Eugene S. Talbot, M.S., D.D.S., M.D. Cloth. Price, $4. Pp. 340, with 102 illustrations. Toledo, Ohio: The Ransom and Randolph Company, 1913.

Interstitial gingivitis or pyorrhea alveolaris is frequently regarded by the dentist as a mere local disease which reveals itself by the suppurative changes in the gums, and is to be treated chiefly by local remedies. The developmental relations of the disease have appealed strongly to the author, however, in connection with his studies in development and degeneracy. He looks at it as a manifestation of constitutional tendencies, having its origin in a disease of the alveolar process of the tooth, which causes the gum to retract; the infection results as a secondary process.

In Talbot's view interstitial gingivitis is divided into two stages: In the first there is an inflammatory process in the bone and teeth leading to absorption of the alveolar process and exfoliation of the teeth; in the second, the gums become infected with pyogenic organisms which cause the production of pus. In the first stage the etiologic agents are toxic irritants which reach the tooth through the blood, in the second the agents of infection attack the gums from the mouth cavity. Attacking the disease by purely local measures, especially disinfectants, can only palliate the effects without reaching the cause of the disease. Hence the author's therapy includes, in addition to constitutional measures, local methods that are directed to the initial stage of the disease and aim to excite a healthy hyperemia by the application of iodin to the gums and vigorous massage with the tooth-brush. In applying iodin he is incidentally using a powerful disinfectant, so that his treatment meets the indications drawn from the infective nature of the later stages of the disease. Vaccine treatment does not meet favor in the author's eyes. He urges that the vaccine is not likely to correspond to the pyogenic germ that causes the suppuration. At any rate such treatment could affect only the suppurative lesions and not the underlying bone disease.

Whether or not some of the experimental work in this volume will fulfil the strict requirements of scientific accuracy may be questioned. For instance, observations on the degree of acidity of urine are cited with no data as to daily quantity; in which case reliable conclusions can hardly be drawn. Other criticisms may be made, but the fact remains that a view of the relations of the jaws and teeth to the nutrition and metabolism of the whole organism is presented which is worth careful consideration. If mere oral sepsis, as shown by the severer forms of pyorrhea, is capable, as Hunter believes, of producing a grave form of anemia classed among the pernicious forms, it behooves us to know all the contributing causes of this condition of the mouth.

A Text-Book of Midwifery for Students and Practitioners. By R. W. Johnstone, M.A., M.D., F.R.C.S., Assistant to the Professor of Midwifery in the University of Edinburgh. Cloth. Price, $3.25 net. Pp. 485, with 264 illustrations. New York: The Macmillan Company, 1913.

This addition to the Edinburgh Medical Series is a volume in every way worthy of its predecessors. It is prepared particularly to meet the needs of students in a book of convenient size containing all essential information; sufficient attention is given to practical points and to the discussion of the management of normal and abnormal cases to bring the work up to the demands of those actually engaged in the practice of medicine. The introductory material on anatomy and physiology is followed by a consideration of the physiology of pregnancy, labor in the various presentations, the physiology of the puerperium, and the pathology of pregnancy, of labor and of the puerperium. Puerperal infection is the chief topic in the last section, though it includes also interesting chapters on the newborn and on infant feeding. Finally, operative obstetrics is discussed, and the volume is completed by a carefully compiled index. The material presented is given concise expression, and the practical phase of the subject is emphasized. Thus, the complicated theme of the development of the early embryo and placenta has been simplified by the exclusion of references to comparative embryology. Brief references to the literature have been made here and there for the convenience of the student, but no elaboration of a bibliography has been undertaken. On its technical side description of the simple and the more common operative measures has been detailed, while procedures suitable only to performance in hospitals or by specialists have been more briefly set forth. The volume gives compact expression to the Edinburgh School of Midwifery.

A Text-Book of Surgery for Dental Students. By G. Percival Mills, M.B., B.S., F.R.C.S., Surgeon to the Royal Orthopedic and Spinal Hospital, Birmingham, and Humphrey Humphreys, M.B., Ch.B., L.D.S., Demonstrator on Dental Surgery at the Birmingham Dental Hospital. Cloth. Price, $3.50 net. Pp. 340, with illustrations. New York: Longmans, Green & Co., 1913.

This book is for students and practitioners of dental surgery. In view of the fact that the development of modern bacteriology has thrown much light on the relationship of the mouth to the general health, bacteriology has been treated somewhat fully. The chapter on this subject contains probably all that it is necessary for a dentist to know of bacteriology, provided that he will attempt to do only such things as his knowledge warrants. If he is to encroach on medical fields, he will find that more information is necessary for him than is contained in this book. The pathologic and clinical aspects of inflammation are considered in a simple manner, but the discussion on gangrene leaves much to be desired. Thus the treatment of gangrene would seem to concern only the toes and feet, since no mention is made of noma and related diseases of the mouth. The discussions on tetanus, tuberculosis, actinomycosis and syphilis are likewise very poor. Thus, in the advice regarding the treatment of syphilis, in no instance is the statement made that the patient should be referred to a physician. Note also the following statement: "A point of particular importance is the time when it is safe to allow a syphilitic patient to marry. The general rule followed is twelve months after all manifestations of the disease have disappeared." No mention is made of the Wassermann reaction. There are fairly good discussions on tumors and cysts; on goiter; a chapter on diseases of the eye, and other items whose relation to dentistry is not very apparent.

Genito-Urinary Diagnosis and Therapy for Urologists and General Practitioners. By Dr. Ernst Portner, Specialist for Urology, Berlin. Translated by Bransford Lewis, M.D., B.Sc., Professor of Genito-Urinary Surgery, Medical Department of St. Louis University. Cloth. Price $2.50. Pp. 221 with 43 illustrations. St. Louis: C. V. Mosby Company, 1913.

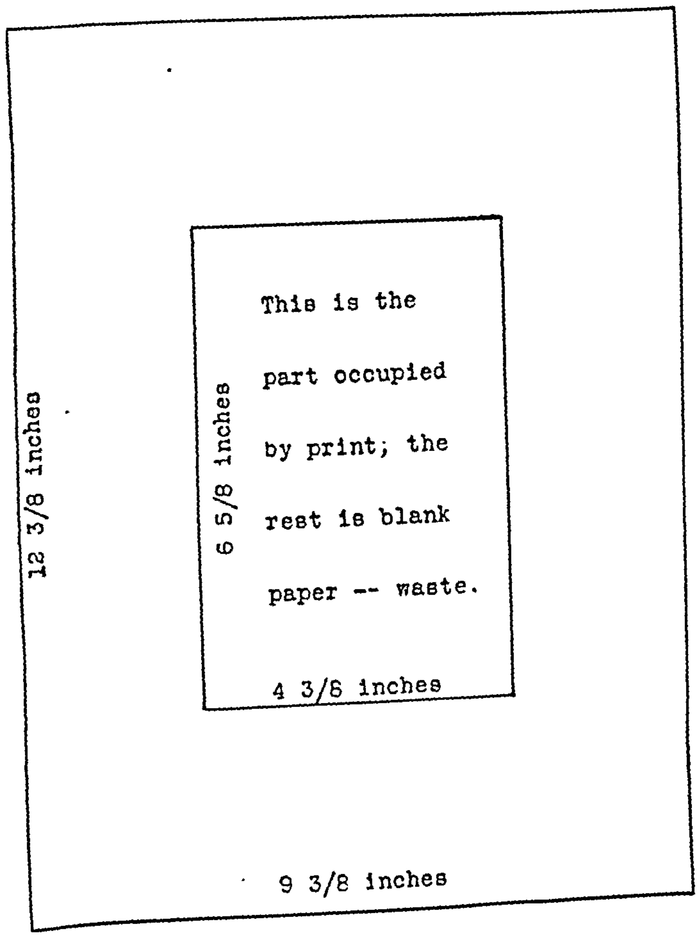
This book presents in a concise form a practical treatment for genito-urinary diseases. It deals entirely with therapy, furnishing the information that the practitioner most desires and needs in the treatment of urinary cases. Pathology, symptoms and diagnosis are mentioned only occasionally and then only to bring out or to drive home a therapeutic point. There is no padding and no attempt is made to give the history of any method of treatment, nor is mention made of a large number of more or less obsolete therapeutic methods. The advances made in the last few years in the study of the gonococcus are discussed fully. The diagnosis and cure of gonorrhea by the use of the gonorrhea complement-fixation test, and the allergy reactions are fully described.

The Origin and Nature of Life. By Benjamin Moore, M.A., D.Sc., F.R.S., Johnston Professor of Biochemistry, University of Liverpool. Cloth. Price, $0.50. Pp. 256. New York: Henry Holt & Co.

All those whose interest in this subject was reawakened by Schäfer's presidential address last year to the British Association will welcome this little book. Like Schäfer, Moore also believes that "life probably arose as a result of the operation of causes which may still be at work to-day causing life to arise afresh." He briefly discusses the genesis of electrons and atoms, chemical evolution in the suns, chemical compounds on earth, building materials for living matter and evolution of colloids, the study of which in the last decade has become the center of feverish industry. Coming to the origin of life on earth he holds that, as the evidence of geology shows, life appears in a cooling planet as soon as temperature will permit. At first it is evident that spontaneous production of such a thing as even a bacterium or other unicellular organism would by no means solve the problem. The new-born cell would have no organic pabulum and must perish. Inorganic colloids must first develop and in turn one of them must begin to evolve, not a living cell, not even a complex protein, carbohydrate or fat, but some quite simple form of organic molecule which must possess the property of transforming sunlight or some other form of radiant energy into chemical energy. Later this simple organic compound would begin to condense and form more complex organic molecules; and finally complexes of inorganic and organic matter would come into existence as crystallocolloids. Thus without any hiatus life would be led up to and inaugurated.

Studies in Cancer and Allied Subjects. Conducted under the George Crocker Special Research Fund at Columbia University. Volume I—The Study of Experimental Cancer. A Review. By William H. Woglom, M.D., Assistant Professor, Columbia University. Cloth. Price, $5 net. Pp. 288, with illustrations. Volume III—From the Departments of Zoology, Surgery, Clinical Pathology and Biological Chemistry. Price, $5 net. Pp. 308, with illustrations. New York: Columbia University Press, 1913.

The first volume contains an extensive and valuable review of the more recent experimental work on cancer. Quite a number of the articles in the third volume have been printed before. They bear more or less directly on the problems of cancer and show that cancer is being investigated by special workers in many departments of Columbia University. As pointed out in the notice of the second volume of this series of reports there are serious objections to the form of the book. The volumes are unwieldy and too large for many book-shelves; the blank margins are so unusually and needlessly wide that only a quarter of the page is occupied by print; three-quarters of the paper is unused. The third volume weighs 4½ pounds; hence about 2 pounds of good, white paper are wasted in every volume to no other purpose than annoyance to the reader and librarian and increased expense for postage and expressage. How will Columbia University justify this foolish waste of the George Crocker Special Research Fund?



This is the part occupied by print; the rest is blank paper -- waste.
6 5/8 inches
4 3/8 inches
12 3/8 inches
9 3/8 inches

Proportion of print and blank paper.

Coprostasis: Its Causes, Prevention and Treatment. By Sir James Sawyer. Cloth. Price 2 shillings 6 pence. Pp. 74. Birmingham: Cornish Brothers, 1912.

Coprostasis is a rather stately Greek title for the familiar subject of constipation. The book consists of two lectures on the subject, and lest one might forget what he said in the first the author repeats much of it nearly word for word in the second. Line upon line and precept on precept is a good proverb, but hardly suited to the temper of the readers of modern medical literature, who are accustomed to look for something new. Sir James deprecates the use of drugs, but when ordinary methods, of which he recommends diet, exercise, and a suitable position during defecation, are exhausted, he resorts to them; and drawing from his own extended experience he recommends aloes as if it were almost a personal discovery. The author is fond of honey; he tells us that it should be pure, that in his county excellent honey is furnished by the Warwickshire Beekeepers' Association, and that it may be spread on bread. He also permits the use of ginger-bread and biscuits, and even suggests making them with oatmeal instead of wheat flour. Further he says, "As to beverages, either oatmeal water or prune tea are helpful and may be drunk hot, warm or cold." All this is, to be sure, very good advice, but the reader is continually tantalized with the hope that some new method will soon be mentioned. Even his favorite crouching position in defecation is not new. It is bad enough to have had such stuff once encumbering the pages of the *Lancet*, but to publish it in book-form is too much. The author highly recommends the enema, but says that it can be given properly only through an O'Beirne's tube which, it seems, will extend through the sigmoid flexure. We wonder whether he has ever confirmed this by the Roentgen ray! Other workers appear to have failed in this attempt. There are perhaps some important hints in the book, but we have failed to find them. It would have saved trouble to the author and the reader to have printed them separately and to have thrown the rest away.

Applied Bacteriology for Nurses. By Charles F. Bolduan, M.D., Assistant to the General Medical Officer, Department of Health, New York City, and Marie Grund, M.D., Bacteriologist, Research Laboratory, Department of Health, New York City. Cloth. Price, $1.25 net. Pp. 166, with 62 illustrations. Philadelphia: W. B. Saunders Company, 1913.

The subject of applied bacteriology is presented clearly and concisely in this book, which is written in an interesting and readable style. There are two main heads—general bacteriology and special bacteriology. Under the first are chapters on the character of bacteria, the methods of studying bacteria, the preparation of stained smears, the cultivation of bacteria, disinfectants and antiseptics, sterilization by heat, relation of bacteria to disease, transmission of infectious diseases, and immunity. In the chapter on the transmission of infectious diseases great stress is laid on "carriers" and little on "fomites." To quote: "The knowledge we now possess on this subject proves that infectious diseases are transmitted by persons rather than by things, by contact with others, by certain discharges of those who are infected and by insects and vermin." The division on special bacteriology includes the various infectious diseases, bacteriology of milk, fermented milks, bacterial food poisons, bacteriology of water, animal parasites, practice of disinfection, collection of material for bacteriologic examination, and other important pathogenic micro-organisms. The work is not too technical and treats the whole subject in such a way as to be entirely suitable for the use of training schools.

Clinical Pathology. By P. N. Panton, M.A., M.B., B.C., Clinical Pathologist to the London Hospital. Cloth. Price, $4 net. Pp. 446, with 58 illustrations. Philadelphia: P. Blakiston's Son & Co., 1913.

The author attempts to describe in a reasonable compass such laboratory investigations as have a practical bearing on diagnosis and treatment. No list of references is given, and the names of authorities unless definitely associated with a special reaction are for the most part omitted. The text is divided into eight sections—on blood, bacteriology, puncture fluids, urine, alimentary system, eye and skin, respiratory tract and histology. We question whether there is need for a work of this kind. It is neither a book on clinical diagnosis nor a clinical pathology. It contains much of normal histology and laboratory technic and comparatively little of real clinical pathology. Within the limited space of four hundred pages the author has tried to write a number of compends. The most pretentious chapter is the one devoted to bacteriology. There is no evidence of tests or clinical pathology. Twenty-five pages are given over to a consideration of the bacteriologic, chemical and microscopic examination of puncture fluids; thirteen pages are devoted to histologic methods. This work savors too much of the compend, which is not what a work of this size should be.

Disease of the Rectum and Pelvic Colon. By Martin L. Bodkin, M.D., Rectal Surgeon, St. Mary's Hospital, New York. Cloth. Price, $3.50. Pp. 416 with 90 illustrations. New York: E. B. Treat & Co., 1913.

In his description of the anatomy of the anus, rectum and pelvic colon, Bodkin brings out many minor anatomic points that are of paramount importance clinically, the knowledge of which is absolutely essential to a proper understanding of the symptoms, clinical course and treatment of many rectal diseases. The chapters on rectal carcinoma and rectal stricture give well-tried and proved methods of treatment. In the chapter on hemorrhoids, several operative technics are minutely described. The point is made that the treatment should be adapted to the type and the location of the hemorrhoid in each case. Local anesthesia is recommended, and urged in all cases that do not require a stretching of the sphincter. The ordinary pyrography cautery is recommended as efficient and is used by the author in place of the more expensive instruments. The chapters on fissure and fistula give in detail the technic necessary to diagnose and treat these common pathologic conditions. The technic of packing the rectum for hemorrhage by using the Pennington tube is well described and illustrated.

## Construction and Enforcement of Contract with Assistant Agreeing Not to Practice Afterward in Same Town

*(Styles vs. Lyon (Conn.), 86 Atl. R. 564)*

The Supreme Court of Errors of Connecticut affirms a judgment overruling a demurrer to a complaint to enforce a contract entered into between the plaintiff and the defendant, by which the defendant, a physician and surgeon, agreed for a stipulated consideration to take charge of the plaintiff's business as a physician and surgeon in a named town, and that, in case of a termination of the contract, he would not locate or open an office within the limits of the town for the practice of his profession. The contract was made in 1908, for a period of one year, continued, and, in 1912, the defendant left the employ of the plaintiff, and subsequently opened an office for the general practice of medicine in said town.

The continuance of the contract the court says may have been by renewal from year to year, or by general agreement or acquiescence of the parties. If its continuance was under a general agreement or acquiescence, all of its provisions, so far as applicable, remained in force; and such provisions as were inapplicable to the period beyond the term of the original contract ceased to be effective. The only provision of the contract falling within this ineffective class was that providing that the contract should continue "for a period of one year." Obviously this could apply only to renewals of the contract for the term of one year. The provision of restriction was a necessary part of the contract, containing, as it did, protection for the experienced practitioner against the taking away of his practice by his assistant on leaving his employ, in which the assistant had had the opportunity to gain the confidence and favor of the patients of his employer. The continuance of the contract continued the restriction.

A contract of this character, if not against public policy, is valid if it be founded on a legal consideration and be reasonable. A contract in partial restraint of trade will not, as a rule, be held to be against public policy, unless it unduly interferes with the interests of the public. There was no attempt by this restrictive provision to restrain the defendant from pursuing in an extended territory his vocation for either an indefinite or a limited time. The area of restriction was confined to a single city; the rest of the world was open to him. Under such circumstances, it could not be said that the defendant's liberty of pursuing his profession was interfered with to such an extent as to be unreasonable or to work injury to the public. Moreover, the consideration of the contract was a valid one; its adequacy was not open to inquiry in an examination of the legal validity of the contract.

The test of the reasonableness of this contract was met by answering affirmatively the question, Does it afford a fair protection to the interests of the employer in whose favor it is made? The area of restriction was limited to the place of practice. Without the aid of the restriction, the defendant having won the confidence of the plaintiff's patients might breach his contract, and take away from him the very patients whose confidence he had gained while in the plaintiff's employ. There was no other effective way by which the plaintiff could protect himself in his livelihood except by preventing the defendant from wrecking his practice.

The defendant insisted that there is a distinction between a business and a profession; that, while the period of restriction as to a business may be unlimited, the rule should not apply to a profession, since it is a purely personal relation whose benefits cease on death or the cessation from practice. The court does not think the distinction tenable. A profession partakes on its financial side of a commercial business, and its good will is often a valuable asset. It is true that the profession has its personal side, but it is not true, except under exceptional circumstances, that a professional man is indispensable to any community. The distinction sought is made in a few cases, but generally the courts do not recognize it and almost uniformly follow the rule that the mere fact that the duration of the restriction as to time is indefinite or perpetual will not of itself avoid the contract if it is limited as to place, and is reasonable and proper in all other respects.

The authorities generally are in accord on the rule of law governing this action. A contract between an employer and employee providing for the restraint of the latter, after ceasing to be in his employ, from continuing in a similar employment, will be sustained if it be not against public policy, and be not unreasonable under the circumstances of the case, and be made on good consideration. The facts of the complaint—and each case must be governed by its own facts—showed no circumstances of hardship attendant on the making of the contract and no advantage taken of the employee and no wider restriction than was reasonably necessary for the protection of the employer; therefore, the restrictive covenant could not be held to be unreasonable.

The restriction, though in specific terms not limited in time, was by the fair construction of other provisions of the contract limited to the lifetime of the defendant. Whether if the plaintiff had ceased to practice his profession, and had not transferred his practice to a successor, a court of equity would enforce the restriction in his behalf need not be determined, for the facts as admitted by the demurrer did not present that case, but one in which the defendant had remained in the plaintiff's employ for four years, and the plaintiff had resumed his practice, and was seeking to protect himself in his practice by having the restrictive provision of his contract enforced. Some of the authorities hold, and not without apparent reason, that when the professional man has ceased to practice, the enforcement of the restriction would not benefit him, and would be an unreasonable hardship on the covenantor, and therefore the restriction is, under the then circumstances, unreasonable, because it has ceased to furnish a fair protection to the covenantee. The hardship of enforcing a contract in behalf of one who has no present benefit from the contract and no reasonable probability of any in the immediate future would incline a court of equity to hold such a construction of the contract without the fair intent of the parties to the contract and lead it to refuse its aid.

### Liability for Leaving of Sponge in Abdominal Operation—When Responsibility Cannot Be Put on Nurses—Effects of Pleadings

*(Palmer vs. Humiston (Ohio), 101 N. E. R. 283)*

The Supreme Court of Ohio affirms a judgment for $5,000 damages rendered in favor of the plaintiff for alleged malpractice in negligently leaving a sponge in the performance of an abdominal operation. The court says that the pivot of this case was in the particular pleadings, especially the defendant's answer wherein he admitted the contract to perform the surgical operation, and admitted that "in the performance of said operation it was necessary that certain gauze or cheese-cloth sponges be used." The issues of a case are defined by and confined to the pleadings. Under the pleadings of this case the use, care and removal of such sponges were a part of the operation contracted for. In such a case the use of the sponge becomes a part of the operation as much as the use of knife or needle would become a part of this operation, and, if the use of the sponge be a part of the operation, it must follow as a corollary that the removal of the sponge at the end of its use becomes also a part of that operation.

By way of further illustration and argument, suppose that in the operation a large number of instruments was used, and, in addition to keeping tab on the number of sponges, the head nurse or some third party had kept tab on the number of instruments used and placed within the body, and had made an error in the count, whereby one of the instruments was left in the body; would it be seriously contended that this was not a part of the operation, and that the surgeon was not liable, but that the nurse alone was liable?

The defendant, therefore, having admitted the contract to perform the operation and the use of the sponges as necessary thereto, assumed the full measure of professional responsibility, which is the average care and skill of the profession at the time and in the place of the operation, which must include everything connected with the operation, the use of foreign substances, and also the removal of those foreign substances when the operation is finished.

The defendant undertook to excuse himself from that full measure of care and skill personally by claiming through his counsel that in the performance of such operation it was necessary in careful and skilled surgery to secure the assistance of certain nurses, interns and associate surgeons in and about the hospital, and that included among these was one Miss Kelly, the head nurse, to whom he intrusted the duty of counting the sponges before putting them into the body and on removing them from the body, and that he relied on the accuracy of her count, and that, if there was any error in her count, he, the surgeon, was not responsible. This was a hybrid sort of confession and avoidance, first confessing that he contracted to perform the operation, and that in connection therewith and as a part thereof it was necessary to use sponges, etc., and then, for the purpose of avoiding his full measure of professional and legal liability, contending that, if there was any negligence in failing to remove any sponge, such failure was the negligence of the nurse who did the counting, the adding and the subtracting of the sponges. But no such issue was raised by the pleadings. The defendant could not in his answer admit the employment to perform the operation and admit that in the performance of said operation it was necessary that certain gauze or cheese-cloth sponges be used, and then thereafter undertake to say that that particular part of the operation involving the use of those sponges was in somebody else's hands or head, for whose negligence, if any, he, the operating surgeon, could be held responsible. The defendant must stand on his contract of employment, and his negligence must be determined accordingly. If he was responsible for the proper use of the sponge, about which there could be no doubt under the pleadings and the inferences and deductions which must follow from them, he was likewise responsible for the proper removal of the sponge. The one must follow the other in logical sequence and legal liability.

If one is pleading a defense to a contract set forth in the petition, he may, first, deny the contract; or, secondly, he may admit it and say its terms have been fully kept on his part; but if he admits the contract, and avers that he has fully performed, he cannot thereafter claim that he secured a waiver of certain parts of it. In order that the waiver can avail him, he must plead it. Third, in order that he may stand on a supplementary contract, he must plead it. Fourth, if he is relying on a professional custom or usage obtaining among good surgeons at the time and in the place in which the operation is performed, which would avoid the liability charged, he must specially plead that particular usage or custom, and his pleadings in general must be harmonious and consistent; that is, the particular custom or usage must not conflict with or contradict the remainder of the defendant's pleading.

In this case there was no issue of agency. In order to make evidence relative thereto available, and to excuse the surgeon from any negligence on the part of the head nurse or any of his assistants, it was necessary to specially plead such usage or custom then generally in use at the time and place of the operation.

The record unmistakably presented the ghastly fact that a large gauze sponge, 14 inches square, was left in the abdomen just under the abdominal wall for more than six months after the operation. Whether this fact was due to the negligence of the surgeon, whether it caused the plaintiff any of the great pain and suffering, physical and mental, set forth in the pleadings, what the amount, if any, was her damages, were all properly questions for the jury and the courts below. With these this court has nothing to do.

### No Case Made Against Roentgen-Ray Specialist—Limit to Doctrine of Res Ipsa Loquitur

*(Sweeney vs. Erving (U. S.), 33 Sup. Ct. R. 416)*

The Supreme Court of the United States affirms a judgment in favor of the defendant in this action to recover damages for personal injuries sustained, as was alleged, through his negligence in the making of certain Roentgen-ray tests on her body with the use of apparatus owned and operated by him. The plaintiff adduced evidence tending to prove that she was under treatment by a Dr. Kerr for the fracture of a rib, claimed by her to have been caused by the negligence of a railway company, which denied the existence of such fracture, and that Dr. Kerr arranged with the defendant, a specialist in the use of the Roentgen ray for diagnostic purposes, for a Roentgen diagnosis to be made by him, and that on her fourth visit to his office she suffered a Roentgen-ray burn. The court does not consider that there was error in a refusal to instruct the jury at the plaintiff's request that, "If you believe on the evidence that in the course of the operation of the Roentgen apparatus by the defendant the plaintiff was burned, that fact is of itself evidence of negligence on his part, and casts on him the burden of proving, if he can, by a preponderance of evidence, that the plaintiff's injury was not caused, in whole or in part, by his negligence; and in such case, unless you find by a preponderance of the evidence that said injury was not caused in whole or in part by the defendant's negligence, your verdict should be for the plaintiff." Instead, the jury was instructed that "the burden of proof is on the plaintiff to establish by a fair preponderance of the evidence that the burn on her back was caused by negligence on the part of the defendant in the manner in which he subjected her to exposure by the Roentgen ray." The plaintiff's special reliance was on what is called the doctrine of *res ipsa loquitur*, or the thing speaks for itself. But, in the court's opinion, *res ipsa loquitur* means that the facts of the occurrence warrant the inference of negligence, not that they compel such an inference; that they furnish circumstantial evidence of negligence when direct evidence of it may be lacking, but it is evidence to be weighed, not necessarily to be accepted as sufficient; that they call for explanation or rebuttal, not necessarily that they require it; that they make a case to be decided by the jury, not that they forestall the verdict. *Res ipsa loquitur*, when it applies, does not convert the defendant's general issue into an affirmative defense. When all the evidence is in, the question for the jury is whether the preponderance is with the plaintiff.

Again, the court says that it did not appear that there was any evidence on which the jury could properly base a finding that there was danger of injury to the plaintiff by reason of her condition or of any other matter tending to predispose her to such injury; nor to sustain a finding that such possibility was known to the defendant, or by proper study or inquiry should have been known to him. Nor could it be said, as matter of law, that the defendant had undertaken any duty requiring him to make special study or inquiry respecting the plaintiff's condition or the possibility of injury to her, or to advise her of such possibility of injury; for there was testimony that would have warranted a finding that Dr. Kerr had assumed the responsibility of advising the plaintiff respecting the propriety of her submitting to the operation.

## COMING MEETINGS

American Physiological Society, Philadelphia, Dec. 27-29.
Society of American Bacteriologists, New York, Dec. 31-Jan. 2.
Southern Surgical and Gynecological Assn., Atlanta, Dec. 16-18.
Western Surgical Association, St. Louis, Dec. 19-20.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

*Meeting held Oct. 27, 1913*

First Vice-President, Dr. T. Passmore Berens, in the Chair

### Neoplasms of the Bladder; Operative Treatment

**Dr. Francis R. Hagner**, Washington, D. C.: All tumors of the bladder are clinically malignant. Unless they are removed by some operative means they either directly or indirectly cause the death of the patient. At present all seem to be agreed that the Oudin current offers better chances of success than any of their earlier treatments. It is imperative to examine these patients cystoscopically at regular intervals, and to remove at once any evidence of recurrence. My method was first published in November, 1910.

### DISCUSSION

**Dr. Edward L. Keyes, Jr.**: My statistics compare very favorably with those of Dr. Hagner, but one cannot deny that his method gives new hope in desperate pathologic conditions. The disparity between pathologic conditions presented and the general condition in these cases has more than once been forced on my attention. Many cases do not permit of an early diagnosis because there are no symptoms present. In many cases the high-frequency current is of no use. The tumors that can be aided by the high-frequency current are those that are clinically benign. There are several characteristics which aid one in differentiating benign and malignant tumors, two of which are of special importance. The first is the sloughing on the surface of the tumor. Such tumors can be controlled by the high-frequency current. Clinically they are malignant. In the second place there is the tumor of very virulent and intractable form, with which cystitis occurs with an infiltration of the bladder wall. It is impossible to see these tumors without the aid of the cystoscope. Because of the cystitis the use of the cystoscope is very painful. These are the cases that cannot be controlled by the use of the high-frequency current. It is obvious that tumors that can be seen or felt through the rectum cannot be controlled by the high-frequency current, and these are the cases that should be subjected to a radical, open surgical operation.

**Dr. Leo Buerger**: One point brought out by Dr. Hagner should be particularly emphasized, and that is the importance of an early diagnosis. In the treatment of these cases it is most important to know whether the pathologic examination shows the growth to be a carcinoma or a papilloma. The safest data in making the diagnosis of carcinoma of the bladder are those revealed by the cystoscope. When the papilloma is single, pure fulguration should not be employed, because it is slow. One should bite off as much of the base of the tumor as possible, as well as some of the surrounding tissue. If the tumor grows deeply in the muscular tissue it is carcinoma. If atypical cells are present the tumor is a carcinoma. Another important point was that there was in these cases an area of edema, and the microscope would show edema plus carcinoma. In every case one should look for this edema.

**Dr. Alfred T. Osgood**: The impression that the entire symptom-complex, or at least the cardinal symptom, must be present before tumor is suspected, seems to prevail. Tumor may exist in the bladder without symptoms or the signs of slight vesical irritability. Symptoms of cystitis are frequently due to or caused by the presence of tumor of the bladder. The cardinal symptom of hemorrhage is very frequently absent entirely and for a long period of time. Sometimes these cases are treated for months or even for years before a tumor of the bladder is discovered. It is the early diagnosis of these malignant tumors that I wish especially to emphasize. Many of these can be helped only by an early discovery of the cause of cystitis.

### Indications in Renal Surgery which Demand Immediate Operative Intervention

**Dr. Louis E. Schmidt**, Chicago: In a general way the urgent cases requiring immediate operation are those in which the conditions in or around the kidney threaten that organ with destruction, or if no relief by operative interference is given the general condition becomes so involved that the termination in most cases is fatal. Hemorrhage, no matter whether produced by injury or in the course of nephritis, tuberculosis, stone or neoplasm, gives rise occasionally to immediate intervention. The same may be said of anuria. It is, however, to the different types of acute nephritis that attention is especially directed. These are: (1) The acute parenchymatous type, which is produced by all well-known infectious diseases; (2) the acute suppurative type, which is exemplified so well by the colon bacillus infection, and (3) the acute toxic type, which is produced by many drugs and toxins. The significance of the passage of bacteria really has not been positively established, but it is my opinion that it is a distinct sign of the involvement of the kidney. Decapsulation probably relieves intrarenal tension, but it is improbable that it relieves intrapelvic tension or edema of the kidney so thoroughly as an incision through the organ into the pelvis. It is an absolute fact that urinary findings may be completely negative even in extreme cases.

It is impossible for a one-sided acute infectious nephritis to occur; if such an acute condition persists for any length of time certain agents are produced in the course of the destruction of the kidney which destroys the kidney cells. These bodies of nephrotoxic character, after gaining access to the circulation, are not only at once the source of the greatest danger in destroying the kidney cells of the involved side, but are equally important to the opposite side, producing similar destruction of the otherwise healthy kidney. If the process is not too far advanced there is at least only the destruction of a certain amount of kidney tissue. With the hope in view that the operative procedure will stop the further progress of the destruction of the kidney and of its opposite, there is also hope that by the operation the consequences to the system in general may be avoided. Under the circumstances the correct course to pursue is to undertake operative measures, particularly when all known conservative treatment has been of no avail. These procedures may vary as to the indication. In the severe hemorrhages the operative procedure should be guided by the condition, and this also holds true in cases of anuria. In groups 1 and 3, after all medical means have been used at least for a short time, operative interference is desirable and decapsulation is the operation of choice in these cases. If operation should be decided on in cases of acute infectious nephritis, especially in colon infection, the kidney should be exposed. If the involvement has not progressed too far, nephrotomy is the operation of choice; otherwise a nephrectomy should be performed.

### DISCUSSION

DR. GEORGE E. BREWER: We are all as yet unfamiliar with the indications for operation in certain renal conditions, especially those which demand immediate operative interference. There is no question in my mind but that there is abundant proof that micro-organisms in the blood may pass through the healthy kidney without producing structural changes. But, on the other hand, they may produce changes from sloughing, swelling, infiltrations and even destruction of the organ. What changes occur depend entirely on the virulence of the organism and the resistance of the kidney tissues. There is no doubt that any kidney that has been subjected to disease, or injury, or anything that causes hyperemia, is a kidney that is vulnerable to these organisms. As they attempt to pass through they may find lodgment and form an abscess. There are two general classes of these cases to be considered, the ordinary acute form and the hyperacute form. In the first class the patient is moderately ill and presents the text-book appearance of pyelonephritis or suppuration of the kidney, with which all are familiar. There is another class of cases so virulent that the patient dies before such changes as have been enumerated can occur. In this type the process is so virulent that even renal symptoms are not present. There is usually a beginning chill with a sharp rise of temperature to 104, 105, or 106 F. Associated with this there is intense prostration and pain on the affected side; this pain is often referred to the anterior abdominal wall, which is very misleading. An examination of the urine would show no particular change because the function of the kidney has been entirely suspended. Centrifuging the urine almost invariably will disclose a few blood-cells and often a trace of albumin. In these cases prompt surgical intervention is the only resource. In the staphylococcus or pneumococcus infection the type of the infection is so rapid that unless the kidney is promptly removed the patient will die because of the pronounced toxemia from the kidney, or a toxemia resulting from metastatic abscess in other parts of the body. These are the cases that demand immediate surgical intervention. A careful urinary examination should be made in all these cases with centrifuging.

DR. JOHN F. ERDMANN: In certain instances of streptococcus infection of the kidney there is a possibility of mistaking the condition for gall-bladder trouble or infection of the liver. Clear bile will be found. On careful palpation of the kidneys a pyelonephritis may be determined. If a nephrectomy is done fewer of these patients would be lost.

DR. J. BENTLEY SQUIER: A woman entered the hospital because of frequency of urination and hematuria. She was acutely ill for a time and then the condition subsided, but came on again, the hematuria being very profuse. An exploratory operation was resorted to, but no condition was discovered which called for the removal of the kidney, so it was sutured back in place, decapsulation having been performed. The frequency of urination and tenesmus disappeared and the patient was perfectly comfortable for eighteen months, when the hematuria again appeared. The kidney was again exposed and was found embedded in a dense adherent capsule. Nephrectomy was performed. On section the condition was found to be a typical case of essential hematuria with chronic arteriosclerosis. The decapsulation operation was merely palliative and resulted well until the adhesions and fibrosis formed. In a second case coming under my notice the patient was relieved for two years by decapsulation, when there was a recurrence of the symptoms. The report of these two cases does not prove anything conclusive, but I believe that with more experience with decapsulation we will find it to be a palliative operation and not by any means a curative one. Decapsulation is applicable to anuria as well as to hematuria.

## MEDICAL SOCIETY OF VIRGINIA

*Annual Meeting held at Lynchburg, Oct. 21-24, 1913*

*(Continued from page 1930)*

### Intracranial Traumas at Birth

DR. JOHN F. WINN, Richmond: A fundamental necessity in the prevention of this accident is more clinical training of students, and some satisfactory disposition of the question of ignorant midwives. Hemorrhage is not necessarily dependent on bone lesions. Pressure may arise from hemorrhage or fracture, or from external pressure on the cranium without fracture. Overlapping of the parietal bones is the chief cause of hemorrhage. Respiratory embarrassment is a factor in the production of intracranial hemorrhage. Cardiac irregularities are often a sign pointing to conditions productive of hemorrhage. The "blue baby," especially, must be watched. The effusion of a considerable amount of blood may occur before signs of increased pressure appear. Thus, two or more days may elapse before the condition can be recognized.

In the prophylaxis of the condition I would emphasize: More routine practice of pelvimetry and fetometry on every primipara and every multipara with a history of dystocia or stillbirth. Accurate diagnosis of the presentation and position of the child prior to labor, and certainly when labor begins, coupled with a thorough knowledge of the mechanism of the contracted pelvis. The cultivation of that watchful expectancy which is necessary for the recognition of the indications of dystocia. A more intimate knowledge of the indications for and correct application of forceps. Forceps should never be used to pull down the unmolded head. Failure to remember that sudden or prolonged pressure by forceps results in dangerous compression of the child's brain. The unskilled use of forceps is more often the cause of compression than the rather infrequent high degrees of pelvic contraction. Routine and careful study of the fetal heart-tones will result in the diminution of this accident. The more general practice of the simple operation of symphysiotomy will likewise reduce the number of asphyxiated infants and cranial accidents.

### *Birth-Trauma in Epilepsy and Insanity*

DR. BEVERLEY R. TUCKER, Richmond: Epilepsy attributable to birth-traumas should be classed as jacksonian. I am inclined to believe that there is a cerebral cell lesion in every case of epilepsy, and that there is no such thing as an idiopathic type. Many cases are due to birth accidents, though the figures are not reliable. The date of appearance varies from very early infancy to adult life. In going over my records, I found fifteen cases apparently definitely due to birth palsy, varying between the ages of 13 months and 25 years. Cesarean section on the mother might have prevented some cases. We should not look lightly on the use of forceps. No person can have an epileptic fit without having a brain-tissue that is susceptible. Likewise, no person can become insane without brain-cell abnormality, except those due to toxins. Are not the failures of surgery due to delayed operations? If the operation were done early, many cases of epilepsy might be prevented. The first attack is usually not given enough consideration. As a cause of insanity I have been unable to fix definitely in my mind cases certainly due to birth-trauma. Some recent cases showing definite changes in the pituitary body showed definite improvement under the use of the hypophyseal extract. I believe that many more cases could be saved by surgical means, especially with the cooperation of the general practitioner, rendered immediately after the first convulsion.

### Surgical Treatment of Birth-Trauma

DR. CHARLES H. FRAZIER, Philadelphia: Hemorrhage in the new-born is almost always subdural, as in the adult. Instrumental delivery does not play so important a part as ordinarily supposed. One of the greatest difficulties in recovery is that the hemorrhage is so often bilateral. The determination of the location of the hematoma is the crux of the situation from the surgical point of view. Those above the tentorium are more easily recognizable than the subtentorial because the muscular symptoms are more prominent. In the subdural type, lumbar puncture will usually show signs of hemorrhage. It is further necessary to ascertain whether, in the pretentorial cases, the hemorrhage is unilateral or bilateral. Lumbar puncture should be done in all suspicious cases and also in cases in the subdural spaces of both sides. The first indication is to relieve the pressure. A small piece of muscle applied to the bleeding point will satisfactorily control the hemorrhage in most cases. To attempt to control it with ligatures is a difficult matter. The operative mortality is over 50 per cent. and will of necessity always be high. It should not be considered prohibitory. The ultimate prognosis has not been recorded.

The mentally defective, of either high or low grade, present no surgical aspect. The care for the increasing number of feeble-minded children is the most important economic problem of health boards. Spasticity is very different. Section of the posterior roots of the cord does relieve spasticity. It is not wise to do it in children of unsound mind, or for affections of the upper extremity. For some unexplained reason, the results are not comparable with those in the lumbar region. In the latter, in selected cases, it is unquestionably of benefit. The residual power is the influencing factor. It may be very difficult to tell. Generally speaking, at least five roots should be divided, usually the three lower lumbar and the first two sacral. Identifying the nerves is difficult, and shock a danger. Disappointment may result unless arrangements are made to reeducate the muscles over a period, it may be, of months.

The cases of epilepsy with general, as against focal, symptoms, are not suitable for surgical interference. Neither are they if it has persisted for years. But in the jacksonian, and in those cases in which the motor symptoms are worse than the psychic, surgery is often helpful. It is a mistake to estimate the advantage until at least five years have elapsed. The tendency to improvement at first is well known. It is extraordinary how extensive the lesion may be without any other symptoms than epileptic seizures. The most that can be said is that in exceptional cases operative intervention may prove beneficial. Rarely are the attacks entirely interrupted; more often they are reduced in frequency.

### Discussion on Birth-Trauma

**Dr. A. Barnes Hooe**, Washington, D. C.: Attention to the patient during pregnancy will prevent most cases of instrumental delivery and, therefore, of trauma. How many men to-day in general practice ever think of using a pelvimeter, or of examining a woman to see if there is a deformity? It is the duty of every man, as soon as he is engaged, to make himself acquainted with the conditions of the pelvic cavity.

**Dr. J. Bolling Jones**, Petersburg: I very seldom use a pelvimeter. I use the hand. We do not hesitate to cleanse our hands and do surgery, and, if we would only look on all obstetric cases as surgical, I do not see why we cannot cleanse our hands and make examinations when necessary. A pelvimeter is necessary, but I do not hesitate to say that the best is the index-finger, and I use it with impunity, provided it is surgically clean.

**Dr. J. Shelton Horsley**, Richmond: In very young children the sinuses are usually not adherent to the bone, and the mechanical details of operation are easier than in the adult. Necessarily, though, the operation is quite dangerous. It has to be done quickly and gently. Very often little dents will come in a child's skull without a fracture. A few slight strokes at the edge, or an elevator underneath, will pop it up like a dent in a derby hat. I do not believe that such a dent should be left uncorrected. If it is necessary to open the cortex, we cannot be too gentle. There is nothing that will injure the cortex so easily as dry gauze. It should be gently irrigated, or cotton or gauze soaked in solution used.

**Dr. Hugh M. Taylor**, Richmond: It is all-important to bring this subject to the general practitioner. Its whole fate is in his hands. If he is watching for these cases, he will recognize them. If the indications for decompression could be recognized and carried out successfully, we would close the doors of the epileptic and similar institutions. If we could trace back not only the epileptic, idiotic and insane, but all these abnormal children, classified as such in school, it would be found that the recognition of the condition by the general practitioner is the key to the whole situation.

**Dr. Greer Baughman**, Richmond: I think that 50 per cent. of epilepsy would cease if all cases of pregnancy were examined by pelvimetry and externally at the end of the sixth month. The necessary knowledge of the pelvis should be acquired sufficiently long before the delivery so that you can prepare yourself. The internal measurement is not needed if we have a normal external measurement, save in the most exceptional cases, so that at the end of six months we can determine and prepare to do what is necessary.

**Dr. Virginius Harrison**, Richmond: We are generally taught to believe that these cases are instrumental. Mine have been chiefly rapid deliveries with a very small child or a very large pelvis. I think it is well to keep that in mind, so we shall not think that because no instruments were used, there is necessarily no brain trauma.

**Dr. Charles A. Saunders**, Norfolk: You can measure the passage, but I do not see how you can measure the passenger. I do not see the value of measuring the one if you cannot measure the other.

**Dr. John F. Winn**: Some comparative estimate may be made of the size of the head and pelvis by vaginal examination. Examination made in the sixth month will make unnecessary frequent examinations during labor. It is not so much the cases of high degree of contracting that embarrass us. They are plain; we know what to do. It is the cases known as border-line.

**Dr. Beverley R. Tucker**: The number of children delivered by midwives occurs to me as a possible explanation of so many cases of epilepsy arising from birth-trauma. When an obstetrician is at a labor case he performs a service just as important as when a surgeon removes an appendix. All men who have seen epilepsy will bear out the statement that if you want to do anything for epilepsy you must do it early. Seven out of ten I have seen were told it was due to indiscretion in diet, or some senseless thing like that. From whatever point you are going to investigate it, start just as soon as the convulsion first takes place, and never lie to the family or fool yourself. If the attack is accompanied by convulsion and unconsciousness, it is epilepsy and the diagnosis is easy. The mother would make it herself if she were not persuaded by the physician.

### Prevention of Malaria

**Dr. Frank H. Hancock**, Norfolk: The Virginia Society for the Study and Prevention of Malaria makes a special appeal to the laity in Norfolk. The society has provided moving pictures showing the marshes before drainage swarming with mosquitoes, and after drainage with the mosquitoes gone. Another film to be exhibited is to show the appearance of the people living in the affected districts and their improvement after the mosquito has been exterminated.

### Intussusception

**Dr. William Goodwin**, Charlottesville: Success in treatment will depend on early diagnosis of the condition by the general practitioner, and the patient's reaching the surgeon for an early operation. Sudden paroxysmal pain, and the vomiting of blood, with little or no fecal matter, should warrant tentative diagnosis. A mass may, or may not, be felt. It would be better to operate in a case of colitis than not to operate in intussusception. In adults the condition is more difficult of diagnosis. The surgical nature, however, can be made out, and the indications are for laparotomy. All patients should be operated on. In young children, after forty-eight hours, the prognosis is bad. The mesentery, if elongated, should be shortened to prevent recurrence, or the cecum may be attached to the lateral abdominal wall.

DISCUSSION

Dr. Stephen H. Watts, Charlottesville: I wish to emphasize the importance of reducing the intussusception by the method of Senn—pressure on the intussuscipiens rather than traction on the intussusceptum.

Dr. J. Shelton Horsley, Richmond: One patient after having a temperature of 105 F. for the first twenty-four hours, recovered; another died within a short while. Two cases were resected; one though easily reduced was resected, bearing in mind the fatality referred to previously. Children rapidly absorb toxins and become overwhelmed. It has been proved that these toxins are formed within the mucous membrane itself. The squeezing of the bowel, by the telescoping, together with the interference of the circulation, tends to form this toxic material, which has been isolated. If the intussusception is reduced, this overwhelming amount of toxic material may be carried into the circulation and overwhelm the patient, and death follow in a short while. So your troubles are not always over when reduction is accomplished. Therefore, I believe in some cases, even if reduction is possible and gangrene not apparently imminent, it is well to resect and obtain healthy bowel together with an end-to-end suture.

Dr. John W. Dillard, Lynchburg: I saw a baby not quite 4 months old whose appendix was entirely swallowed up in the intussusception. The intussusception was reduced, and the appendix found diseased and blue. The appendix was by actual measurement found to be 4 inches long. The patient made a good recovery.

---

## CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA

*Fourth Annual Session, held in Chicago, Nov. 10-15, 1913*

*(Continued from page 2011)*

### Roentgenotherapy of Benign and Malignant Tumors

Dr. Kronig, Freiburg, Germany: I have treated 350 cases of myomas of the uterus with Roentgen rays. The chief aim is (1) to diminish the size of the tumor and (2) to lessen the severity of the hemorrhage, but without absolute amenorrhea. I have many times attained this end, especially in younger persons, but I must confess that I have seldom gained the desired object. Shrinkage of the tumor begins only when amenorrhea is gradually established, and relapses are frequent if menstruation has not completely ceased. Roentgenotherapy for myomas of the uterus is far superior to operative treatment by means of total extirpation or by supravaginal amputation of the myomatous uterus.

I have treated 254 cases of cancer with Roentgen rays and radium. The material includes those cases treated for the prevention of the secondary growth after operation for carcinoma, as well as those cases in which roentgenotherapy for carcinoma has been used therapeutically. Of this number 150 cases were treated on purely therapeutic lines and without operation. Of these, 140 were treated with the Roentgen ray and mesothorium combined. Of 64 cases of carcinoma, 43 were treated for the prevention of secondary growth almost exclusively with unfiltered Roentgen rays, while 21 cases were treated partly with filtered and partly with unfiltered rays. The difference is striking. While 32 out of 43 patients died of carcinoma, the subsequent history of 20 patients showed that 60 per cent. of the recurrences occurred the first year after operation.

Thus far we have not succeeded in curing a single case of metastatic carcinoma. It is quite possible to produce remarkable retrogressions and checking of the carcinomatous metastases by means of intense radiation of Roentgen rays and radium, but in all cases the carcinoma later spread further. We have not saved a single patient.

DISCUSSION

Dr. Howard A. Kelly, Baltimore: I have used radium in 366 cases, of which 188 were malignant growths, including tumors of all parts of the body—mouth, throat, nose, neck, lower part of the abdomen, the uterus, etc. I have treated forty cases of cancer of the lower part of the uterus, where the disease is apt to spread rapidly. The cases were considered hopelessly advanced and inoperable, and in three of them, after extensive operation, radium was used. In these three instances there has been no recurrence and health has been fully restored. I have also had four cases in which no operation could be done on account of the general condition of the patients. Two of these patients had diabetes, one Bright's disease, and the other a serious ailment which contra-indicated operation. In these cases apparently a cure has been effected. I have had two patients with cancer of the larynx, one of whom has been well for months, and the other appears to have recovered, but is still under observation.

### Diagnosis of Lesions of the Upper Urinary Tract

Dr. Hugh Cabot, Boston: We have now at our disposal methods of diagnosis of lesions of the upper urinary tract and abdomen which are of extreme accuracy. They are not being used with sufficient frequency, and therefore a large percentage of errors in diagnosis are being made. These methods require skill and judgment in their application, and without that skill and judgment they are dangerous.

DISCUSSION

Dr. Arthur D. Bevan, Chicago: We need in each clinic a complete organization, a surgeon, a cystoscopist, a roentgenologist, a competent laboratory worker and an internist. In making a diagnosis of lesions of the upper urinary tract, and in practically all abdominal work, the evidence which we desire to obtain can easily be grouped under four heads according to their value: (1) the history, which in a given case of lesions of the upper urinary tract is more valuable than anything else; (2) proper physical examination, including an examination for tumors, dilatation of the colon with air, cystoscopic examination, catheterization of the ureters, and roentgenograms of the region with or without collargol; (3) the laboratory findings, and (4) in a limited number of cases, exploratory operation.

### Report of Cancer Campaign Committee

Dr. Thomas S. Cullen, Baltimore: Few surgeons have sufficient radium to give it a thorough trial. Extensive doses sometimes cure when smaller amounts have but little effect. Only time will tell what percentage of cases can be cured with radium. At present early surgical procedure affords the best chance for cure. The results obtained from radium must be taken into consideration. At the same time the men who have reported the best results are still urging early operation whenever possible. In the past, attempts to instruct the physicians alone have not produced any decisive results. Hence we must go to the people through the newspapers and magazines. Many popular articles have already appeared. The press has responded nobly to our appeal. As a result the patients are coming earlier. Still there is need of further dissemination of knowledge by means of lectures on hygiene in women's clubs, factories and elsewhere. Further, better records must be kept, hospital statistics must be analyzed carefully so that accurate deductions can be drawn from them, and we must have surgical pathologists to aid in diagnosis. Thorough operations must be insisted on as soon as the diagnosis of cancer is made. Patients who have been operated on must be followed up and the results recorded.

In the years past few cases of cancer of the uterus were cured. Now from 20 to 25 per cent. of patients suffering from cancer of the neck of the uterus who are operated on are permanently relieved. Some of these patients are well thirteen or more years after operation. The results following operations for cancer of the body of the uterus are much more comforting, at least two-thirds being permanently cured. These results are a wonderful improvement on those of twenty or thirty years ago, when nearly all died. When women realize what splendid permanent results may be obtained by early operation, and fully appreciate the necessity of finding out just what is the matter with them, instead of procrastinating until the disease is far advanced, the percentage of permanent cures will be greatly increased.

### Publicity and Ethics

Mr. Samuel Hopkins Adams, New York: The universal agency of popular education is the daily press. Between that great agency of enlightenment and the medical profession there has been raised a barrier fraught with difficulty, the barrier of the unwritten law of the profession, which says to the doctor, "thou shalt not appear in print."

The daily paper, with all its sins, is the one agency by which the medical profession can attain immediate, positive and direct universal education—a saturated solution of enlightenment. Nothing else will do it. There is no sacred reticence required of a doctor other than the reticence that guards the privacy of his patient. The time has come when the old, obsolete ban of silence should be lifted and the propaganda should go on through the agency best fitted to spread it—the daily newspapers.

### Publicity and Education Through the American Society for the Control of Cancer

Dr. Edward Reynolds, Boston: The American Society for the Control of Cancer is composed of prominent members of the profession and of influential members of the laity. It is actively at work in perfecting a wide-spread organization of national scope for the active prosecution of this campaign. It has already been guaranteed, and, indeed, for the most part, has already in cash the large amount of money which is necessary even for initial expense of the organization. It has already under salary a general executive secretary, whose past career is a guarantee of his possession of the necessary power of organization. It plans to work in cooperation with all the existing organizations in the study of cancer and in the promotion of the necessary publicity of all the points on which we already have assured knowledge. It has already been assured of hearty cooperation from the more important of these preexisting bodies, and has received the endorsement of all, or nearly all, of the great national medical associations. It asks the sympathy and effective aid of every member of the profession and of every interested layman and laywoman.

### Education and Publicity Through the Council on Health and Public Instruction of the American Medical Association

Dr. Frederick R. Green, Chicago: What can the Council on Health and Public Instruction of the American Medical Association do to enlighten the public on the prevention and control of disease? The answer is obvious. We can place at the disposal of the American Society for the Control of Cancer and the Committee of the Clinical Congress of Surgeons of North America all of the resources of the council. Through the *Press Bulletin* suitable material on this subject can be placed in the hands of five thousand editors, without any cost to the society or to the committee. Through the speakers' bureau addresses can be given to the public on cancer and its menace. Through the bureau of literature, local pamphlets and leaflets on this subject can be distributed.

The work which needs to be done seems also to be threefold and to be peculiarly adapted to the three organizations mentioned. The first thing is to interest the public, especially the wealthy and influential public, in the problem of the control of cancer. This is a movement for the public welfare, and there is no reason why the public should not assume part of the expense. This is the work for which the recently organized society for the control of cancer is admirably adapted.

The second necessity is the careful investigation of the entire problem of cancer, its age, its race and sex incidence, its relative frequency in different occupations and locations and all of the clinical facts connected with its appearance. This is clearly a clinical and surgical problem.

The third requirement is the distribution to the public of the results of such an investigation. This is obviously a task for the Council on Health and Public Instruction of the American Medical Association, representing as it does the organized profession of the entire country. Through its machinery it can, without any additional expense, place before the public any information which may be desired on this question.

### Educational Value of Cancer Statistics to Insurance Companies, the Public and the Medical Profession

Mr. Frederick L. Hoffman, Newark, N. J.: For the year 1910 the average age at death from cancer and other malignant tumors combined was 59.2 years for the registration area of the United States. For males the average age at death was 60.4 years, and for females, 58.4 years. Considered by organs or parts affected, the average age at death in cancer of the buccal cavity was 63.1 years; in cancer of the stomach and liver, 61.2 years; in cancer of the peritoneum, intestines and rectum, 59.2 years; in cancer of the female generative organs, 53.8 years; in cancer of the breast, 58.3 years; in cancer of the skin, 68 years, and in cancer of other organs and parts not specified, 56 9 years.

Of the mortality from all causes in the registration area, ages 45 and over, the proportion of deaths from cancer is 8.6 per cent., or, respectively, 6.4 per cent. for males and 11.2 for females. During the decade ending with 1911 the cancer death-rate for all ages has increased from 65.8 per hundred thousand of population in 1901 to 83.9 in 1911. The cancer death-rate of males has increased from 48.7 to 64.2 per hundred thousand of population, or 31.8 per cent., and the cancer death-rate of females has increased from 83 to 104, or 25 3 per cent. Considered by divisional periods of life, the death-rates have increased at all ages and for both sexes, with unimportant exceptions, from ages 5 to 14, *inclusive*. For males the increase in cancer during the ten-year period, from ages 45 to 54, was 21 per cent.; from ages 55 to 64 it was 39 per cent.; from ages 65 to 74 it was 40 per cent., and at ages 75 and over it was also 40 per cent. For females the increase in the cancer death-rate from ages 45 to 54 was 11 per cent.; from ages 55 to 64 it was 27 per cent.; from ages 65 to 74 it was 32 per cent., and at ages 75 and over it was 44 per cent.

There is sufficient evidence to sustain the conclusion that in quite a number of cases of suicide the underlying motive was the insufferable torture of a hopeless case of cancer. The recorded cancer death-rate is perceptibly diminished on this account. The mortality from cancer has gradually and persistently increased from a comparatively low rate of frequency to proportions which may appropriately be considered a menace to civilization.

Dr. Ernst Schwarzkopf, of the Surgical Clinic of Prague, found that out of 350 cases of cancer of the breast, 321 were operable and only 39 were not operable. Practically all of the early cases which came to him, say of less than six months' duration, were within the operative group. I have made a special analysis of the experience of the General Memorial Hospital of New York with the following results:

This hospital, during the period 1902-1911, treated 1,337 patients on account of malignant disease. Of this number, 531 were males and 806 were females. Of the total number treated, 460, or 34.4 per cent., were cured; the number of improved was 391. or 29.2 per cent.; the number of not improved cases was 266, or 19.9 per cent.; and 115 patients, or 8.6 per cent., were either not treated or remained in the hospital at the end of the period. There were 105 deaths, equivalent to a fatality-rate of 7.9 per cent.

There are the strongest possible reasons for believing, however, that if the cancer facts, including medical and surgical experience, were brought together in an authoritative form, they would materially aid not only the work of the American Society for the Control of Cancer, but also the various cancer research funds, as well as the individual practitioner in his relations to the patients and the public at large. With this end in view, however, it is necessary that there should be intelligent and active cooperation between the laity and the profession, on the one hand, and the life-insurance companies and the federal and state governments, on the other.

### Outcome of Cases of Cancer Recorded in the Johns Hopkins Hospital

**Dr. Joseph C. Bloodgood**, Baltimore: In eighty-five cases of benign lesions of the lip there were 100 per cent. cures. In lesions of the lip which to the sight and touch seemed benign, but which under the microscope proved to be early cancer, there were nine cures, or 90 per cent. The failure to cure in the one case was due to an incomplete operation on the lower lip. When the lower lip only was removed and not the glands, we have cured but seven patients, or 63 per cent. The failure to cure in four cases was due to the involvement of the glands under the jaw. When the complete operation was performed, there have been twenty five-year cures, or 95 per cent. If the lesion of the lip has had previous treatment and has recurred on the lip, the probability of a cure is reduced from 63 to 20 per cent., from 95 to 60 per cent., and from 50 to 20 per cent. The operation for recurrent cancer of the lip reduces the probability of a cure at least 42 per cent. Similar figures can be duplicated with lesions of the tongue, face, skin of the body and extremities.

In the least malignant forms of cancer of the breast, thirty-five patients were cured five years or more after operation. Fifteen patients came for treatment so early in the disease that a diagnosis of cancer could not be made out until at the operation when the lump was explored. Every one of these patients has remained well five years or more; that is, 100 per cent. of cures have been accomplished when the operation has been in the early stage in the less malignant forms of cancer of the breast. In this form of cancer twenty patients came for treatment late. The same complete operation was performed, but the percentage of cures was but 64 per cent. Results, therefore, in the less malignant form of cancer of the breast were: thirty-five cases, 76 per cent. of cures; fifteen early cases, 100 per cent. of cures; of twenty late cases, 64 per cent. of cures. The percentage of cures for all cases of cancer in which complete operation could be done, and in which the period of time since operation is five years, is now 42 per cent. Five years ago it was only 35 per cent.

In cancer control and precancerous lesions the great hope for increasing the number of cures of cancer and decreasing the number of deaths from cancer lies in the education of the public and the profession as to the significance and potential danger of the precancerous lesion; the education of the surgeon as to the best surgery, and the education of the surgeon and the pathologist as to the recognition of the earliest stage of the beginning of cancer in the benign precancerous lesion. Incomplete treatment in the earlier stage of cancer often yields a worse result than complete treatment in a later stage.

## COLLEGE OF PHYSICIANS OF PHILADELPHIA

*Meeting held Nov. 5, 1913*

The President, Dr. James C. Wilson, in the Chair

### Results of the Treatment of Poliomyelitis by Operative Measures

**Dr. G. G. Davis**: As we become better informed as to what can be achieved by operative procedures in these cases they will be earlier resorted to than at present. A boy of 13 had been paralyzed at the age of 1. The parts involved were the lower part of the trunk and left lower extremity, the back, the region of the hip and almost all of the muscles of the thigh, with the exception of the biceps and one or two of the muscles moving the foot. As he grew older a knock-knee developed. He wore braces for seven years. The first operation was an osteotomy of the femur, done in December, 1910. In the following March an arthrodesis was done to fix the flail-foot. The biceps femoris tendon was loosened from its attachment on the fibula and inserted into the top of the patella; and while the foot was strongly inverted the fascia lata was slit in a longitudinal direction and sewed fast with silk sutures behind the greater trochanter. The boy wore a brace until the various operative procedures had well healed. His walking has improved ever since. The fixation of the ankle eliminated movement at that joint and also to a considerable extent at the joint between the astragalus and os calcis. The mediotarsal joint, in front of the ankle, not being interfered with, allowed the anterior part of the foot to drop somewhat, but not enough to allow the toes to catch in walking. The lateral movement of the foot was also eliminated to a sufficient extent to remedy the tendency to valgus. The transplanted biceps muscle can be seen to contract perfectly, and holds the knee back in walking so that it does not tend to collapse when weight is put on it. The holding of the thigh in a position of internal rotation by fastening the fascia lata to the posterior edge of the greater trochanter corrected the outward turning of the foot in walking.

DISCUSSION

**Dr. J. Torrance Rugh**: In Italy I saw Putti do an operation which to my mind takes the place of arthrodesis for the ankle-joint, especially in cases of this type. He separates the anterior tendons from the muscles high up on the leg. Then a hole is drilled through the tibia and the tendon ends are drawn through this hole and fastened subperitoneally in front of the tibia, some of the tendons being passed through from one side and others from the other side. He thus shortens the tendons and leaves purely tendinous structure between attachment and insertion, and the tendon acts as a ligament and will not stretch. It is the badly degenerated muscle-tissue which stretches. If there is sufficient contractive power on the part of the posterior tendons, the anterior ones can be shortened and the foot maintained in the proper position, or if there are live muscles anteriorly, the posterior tendons are shortened in the same manner and the necessity of an arthrodesis is avoided. Operative measures, of course, should not be undertaken until it is certain that complete, or all possible, regeneration has taken place, and that there is no possibility of return of power in the muscles. Not until about six years after the onset of the paralysis should operative measures be instituted.

### Diet in Psoriasis

**Dr. Jay F. Schamberg**: A careful study was made of the protein metabolism of eight psoriasis patients. On a given protein diet a psoriatic subject eliminates less nitrogen in the urine than does a normal person on a corresponding diet. Patients suffering from psoriasis exhibit a remarkable retention of nitrogen. This retention appears to be proportional, in a general way, to the extent and severity of the eruption. The nitrogen is retained to a greater degree than in any other condition, and on a diet low in nitrogen and insufficient in caloric value, one on which a normal person would fail to maintain equilibrium. Experiments with urea feedings show conclusively that the nitrogen retention cannot be attributed to any disturbance in the eliminative capacity of the kidneys. Patients with extensive psoriasis may lose very large amounts of nitrogen in the exfoliated scales, which consist of almost pure protein.

The retention of nitrogen in most cases is greater than can be accounted for by the protein lost in the scales, and it may persist even after scaling has ceased and the eruption has virtually disappeared. A low nitrogen diet has a most favorable influence on the eruption of psoriasis, particularly when the latter is extensive. A high-nitrogen diet exhibits an unfavorable influence on psoriasis, commonly causing an extension of the eruption. The great proliferation and exfoliation of cells by the skin in psoriasis demand a large supply of protein, which can be procured only from the lymph- and blood-streams. This protein supply may be derived from the ingested food, and a possibility exists that the great demand of the diseased skin for protein may also be satisfied by the protein reserve in muscle tissue, which thus may become depleted and later require restoration. A protracted low-protein diet may diminish the proliferative activity of the skin by diminishing the supply of protein, the principal building material. On the other hand, a high-protein diet may stimulate the proliferative activity of the cells by furnishing an abundant supply of the necessary protein.

7. **Diagnostic Hysterotomy.**—When hysterotomy is justifiable, Dickinson says, still remains a question. He has grave doubts whether any one can answer this in pathologic terms. Personal pride in making a diagnosis without too much surgery should lead to a proper effort to obtain same through complete history, curettage, and perhaps the added opportunity of a manual examination of the uterus, but if by these means, particularly in chronic cases, one cannot be positive as to the contents of the uterus or of the condition of its substance, then in Dickinson's opinion hysterotomy is not only justiable but necessary.

10. **Iodin in Abdominal Surgery.**—From his work experimentally and from clinical observations with iodin in the preparation of the field for abdominal operations, Frank concludes that though tincture of iodin is effective as a means of sterilizing the skin, it has its disadvantages. Should the intestines come in contact with the iodin, adhesions will undoubtedly take place in the area exposed, due to the action of the iodin as an irritant to the peritoneum; when tincture of iodin is used as a means of preparing the field, the utmost care should be taken to avoid such contact by protecting the field beyond the abdominal incision by means of moist pads securely fixed in place, and under no circumstances should iodin or its tincture be poured into the peritoneal cavity. In the normal peritoneal cavity iodin in alcoholic or aqueous solution is in sufficient quantity distinctly toxic.

11 and 13. Abstracted in THE JOURNAL, October 4, p. 1323.

19. **Ovarian Tumor.**—One morning, Carstens' patient, aged 30, ii-para, noticed that her abdomen was unusually large; she took a cathartic without relief, her abdomen increasing in size day by day. Carstens saw her just nine days after the onset of the trouble. On physical examination he found an intra-abdominal enlargement extending from the symphysis pubis to near the umbilicus. When lying on her back it was rounded, dull on percussion and fluctuating; nothing could be felt through the vagina, except that the uterus was apparently normal. Her temperature was 100.5 F. Carstens decided this woman had developed a simple ovarian tumor which had produced no symptoms, and had filled the pelvic cavity until it had grown so large that one night it popped up above the rim of the pelvis, and the next morning the patient discovered enlargement. While the tumor was being forced out of the pelvic cavity, the pedicle became partly twisted, sufficiently so as to interfere with the return circulation; as a result some of the veins had ruptured, and there was a gradual filling up of the sac with blood, and an increased flow of serum which, evidently, occurred also during this time. By moving around, attending to her usual work, the pedicle in a few days became still more twisted and finally the circulation was entirely cut off. The tumor then became gangrenous, and the sepsis began to develop just when Carstens first saw her. The operation was a simple one, there were a few slight adhesions, but special care was taken when the sac was emptied not to contaminate the peritoneal cavity. The sac contained a dark, grumous fluid, having the odor of decomposition. The sac itself was green in spots, showing the evidence of gangrene. The infection was from the colon bacillus. She made a quick and smooth recovery.

27. **Traumatic Erb's Paralysis.**—The only rational treatment of this condition, the authors point out, consists in prompt exploration with such repair of nerve structures as may be indicated in the individual case. If no macroscopic injury is found, practically nothing but a skin wound has been made. After the few days required for healing, the after-treatment may be started vigorously, and with exact knowledge of the condition to be dealt with. If gross injury is found it can be repaired at once and so cause the least loss of time to the patient, and give the most favorable opportunity to the nerves for complete repair. Operation consists in the resection of the damaged areas of nerve, followed by end-to-end suture of the roots and trunks. In bad cases in which the resection has been so extensive that approximation by suture is impossible, resection of the middle of the clavicle will greatly facilitate the approximation. An extremity that will move, even with the clavicle absent or distorted, is very much to be preferred to one that is paralyzed, but with the clavicle intact. After-treatment consists in the wearing of some fixation apparatus for from six to twelve weeks, which shall keep the neck and shoulder of the damaged side in close approximation to favor firm anatomic and physiologic union of the nerves. With the removal of the fixation apparatus the various forms

of physical therapeutics should be systematically employed. Results are late in appearing and will seldom be perfect.

28. **Splenic Anemia.**—Splenic anemia in the author's opinion is a disease entity characterized by a definite symptomatology and pathologic picture, and the so-called "Banti's disease" is its terminal stage. In all probability the primary cause of splenic anemia is a toxemia, the origin of which is to be sought for outside the spleen itself, possibly in the gastro-intestinal tract, but the exact nature of which is as yet unknown. This toxin probably acts primarily or secondarily on splenic cells, causing an hypertrophy and increased activity. This increased splenic activity is responsible for the anemia probably through a decreased resistance of the red blood-corpuscles. The icteric pigmentation is also due to an increased hemolysis. Although the thrombophlebitis of the splenic and portal veins is a frequent finding clinically, they believe, from their own experimental work and that of others, that it is not an essential factor in the etiology. If the theory of a primary toxin is correct, they suggest that the blood coming from the spleen to the liver should be doubly toxic, in that it contains not only the primary toxin, but that also elaborated by the splenic substance.

The authors believe that it is the action of this doubly toxic blood that causes the endophlebitis of the splenic and portal veins with its consequent thrombosis. In all probability these same toxic factors play the important rôle in the production of liver cirrhosis, although the mechanical factor of congestion of the portal system may be an additional cause. Up to the present time treatment other than surgical has yielded only temporary benefit. Splenectomy in the first and second stages offers the only chance of permanent cure. The mortality is 12.5 per cent. Splenectomy in the third stage will arrest the further development of the disease, but will not cause a retrogression of the liver cirrhosis. In a few isolated cases of early cirrhosis permanent cure has followed removal of the spleen. In the past five years mortality following splenectomy when done in the third stage has been 56.25 per cent. The combination of splenectomy and Talma's operation should be the procedure of choice in this stage.

32. **Whitehead Operation for Hemorrhoids.**—Of 185 cases cited by Stone, 31 have been operated on less than five years, 59 from five to ten years, 58 from ten to fifteen years and 37 from fifteen to twenty-two years. The results were perfect in every respect in 134 cases, a percentage of 72.4. The most frequent complaint was disturbance of the sphincter action. This complaint was variously phrased; "weakness of control of the bowel" or "imperfect control" were common expressions, and in many cases the statement was made by the patient that he experienced inconvenience in this respect only when from medication or indiscretion in die there resulted an attack of diarrhea. There were thirty-seven cases in which the muscular control was more or less impaired, but in only one of these was there actual paralysis of the sphincter. This patient developed hemiplegia five years after his operation, hence, Stone doubts that the Whitehead operation was alone responsible for the paralysis of the sphincter. Of these thirty-seven patients there were eight who complained of itching or moisture following the operation, but in most of them this was a temporary condition. A number of patients had been bothered for five or six months by sensory disturbances. In sixteen the itching and moisture is still complained of by the patient. In many instances the annoyance was said to be "slight." In five cases there is a certain degree of stricture; two of these were examined by Stone. One of them did not know that he had a stricture; in him there was found a narrow wire-like ring of fibrous tissue of wide caliber, which easily admitted the index finger and caused no symptoms.

In fourteen cases a recurrence in some measure had taken place. One of these patients had had a perfect result for nineteen years and then developed a thrombotic external pile. Another had two small skin tags remaining from the operation. A third has a small external pile. Another says that there is still "some bleeding." Four others have what they describe as a "little return" of the piles. One patient, in response to letters, returned to the hospital, was readmitted and operated on for an isolated hemorrhoidal polyp, which had developed since his original operation. In five cases there was more or less extensive recurrence of the hemorrhoids, and of these, three were operated on the second time. On one of the three a third operation was made, each of the operations being performed by a different surgeon and by a different method. This patient states that he still suffers from hemorrhoids.

33. **Fixation of Transverse Fractures.**—The plate used by Souttar is of thin sheet, and instead of lying on the surface of the bone is for the most part buried in its substance. For this purpose a slot is cut longitudinally in the two fragments of the bone with a small circular saw. The plate is 1 cm. or more wide and from 5 to 10 cm. in length. The whole of this portion is intended to be buried in the bone. A narrow flange projects from one edge and is to lie on the surface of the bone. This flange may be provided with holes for screws. In other cases it may be preferred to fix it with wires encircling the bone. In most cases screws will be preferred and a special form of screw is provided. They are of steel with a fine thread, as they are intended to engage only in the compact bone. The point is slightly tapered and this portion of the screw is flattened on one side. A sharp edge is thus left, by means of which the thread actually cuts its way into the dense bone. The screw may thus be driven into the bone with great freedom, and scarcely any resistance is encountered till it is actually home. A solid hold is thus obtained which is impossible with other types. The chief advantage of this method is the great solidity of the fixation.

43 The Wetnurse Problem. F. B. Talbot, Boston.
44 Relation of Hospital to Hygiene of Pregnancy. J. L. Huntington, Boston.

37. **Summer Diarrheas in Children.**—The striking fact brought out by the authors is that in every case of infantile diarrhea studied (with the exception of the few fermentative diarrheas) there was a general conformity in bacterial type of the intestinal flora, which was uniformly proteolytic in character. This proteolytic flora forms a striking contrast to that of normal children of similar age, in which the putrefactive activities are minimal. Superimposed on this proteolytic background various of the well-known intestinal pathogens may stand out conspicuously. In the past the isolation of such organisms has sufficed to establish the diagnosis; it now appears that such is not necessarily the case, inasmuch as one or more of them may be present without the production of noteworthy symptoms. On the other hand, cases are met with in which these organisms cannot be found, yet show blood, pus and mucus in the stools and severe toxemia. In these latter cases the flora has been found to be proteolytic in character.

39. **Idem.**—Gas bacilli were found by Kendall and Day in fifty-three of a total of 135 cases of diarrhea during the summer of 1912. This is a much higher incidence than that observed in previous years, although the technic employed for the recognition of this organism was that which has been used throughout these investigations. In 1910, for example, gas bacilli were found in but twenty-two of a total of 293 cases examined. In 1911 thirty-three out of a total of 283 were positive. These statistics emphasize the epidemic tendency which the gas bacillus exhibited in 1912. Even early in the season this unusual frequency of gas-bacillus cases attracted attention, and a study was made of diarrheas of moderate severity due apparently to fat indigestion.

In all, 103 cases of these fat diarrheas were studied with this object in view. Of these, six showed definitely large numbers of gas bacilli. Gas bacilli were found in small numbers in six other cases, apparently, however, without significance. Dysentery bacilli were found in five patients; four of these were of the Flexner type, one of the Shiga type. An organism apparently identical with the Morgan bacillus has been found in thirteen of these. A yeast odor was noticed in a considerable number of cases. The stools when passed were more or less frothy and contained considerable amounts of mucus. A peculiar bacillus, which is tentatively grouped with the pneumobacillus was found repeatedly in thirty-one of these, usually in considerable numbers. Paratyphoid bacilli of the Beta type were found in four cases, bacillus pyocyaneus in two, streptococci in six. Yeasts were isolated from the stools of seven patients. The stools from which these yeasts were obtained did not possess a yeasty odor.

48. **Symptoms of Poliomyelitis.**—The symptom referred to by Colliver is a peculiar twitching tremulous or convulsive movement of certain groups of muscles lasting from a very few seconds to less than a minute. The amplitude of vibration is greater than a tremor, not so constant and long as a convulsion, and more regular than mere twitching, yet it has in it some of the elements of all. It usually affects a part or whole of one or more limbs, the face or jaw, but it may sometimes affect the whole body. He says that the symptom may easily be overlooked in the beginning, as it usually lasts less than a second and does not recur, unless the patient is disturbed, oftener than every hour or so. Later the duration of the spells lengthens, first to a few and then several seconds; at the same time the intervals between become shorter. This condition is often accompanied by a peculiar cry similar to the hydrocephalic. At times there is a slight convulsive movement just like a chill, as mothers say, during which time the child is apparently unconscious, with eyes set for a few seconds. and then he apparently becomes normal again. This short unconscious spell with eyes set may occur without noticeable convulsive movements. It acts thus something like a *petit mal.* Colliver has observed it as a twitching of the lips with tongue running in and out and working of jaw, preceding bulbar cases.

81 Infantile Eczema. B. F. Ochs, New York.

79. **Repair for Vaginal Hernia.**—In Wade's method an incision is made beginning at the lateral mucocutaneous junction of the posterior aspect of the vaginal outlet. The amount of tissue that, without too much tension, may be brought up to the urethra, is estimated, and then the mucocutaneous junction at this point is grasped with a mouse-tooth forceps, and with slight traction a curved incision is made with the convexity directed toward the anus, extending to a point at the same level on the opposite side of the vaginal outlet. A flap of mucous membrane is now dissected upward, and with a clamp held clear of the field of operation. This flap is allowed to remain, and subsequently acts as an umbrella to protect the plastic work done below from the irritating discharges above. By means of the fingers the dissection is continued laterally on either side until a firm fascial layer is made out. Then these layers of fascia, not muscle, are brought together and held with a continuous suture of No. 2 chromic catgut. The superficial fascia is similarly united with the same strand of catgut. The skin is dissected free from the superficial fascia. A clamp is placed at the posterior angle of the skin incision and the wound is securely sealed with from four to seven clips. The clips are removed at the end of six to nine days.

102 Expectant School Diseases. H. B. Wood, Providence, R. I.
103 *New Apparatus for Proctoclysis. W. D. Miningham, Newark, N. J.

99. **Aurometer.**—The aurometer designed by Lubman consists of circular headband adjustable by a thumbscrew to fit any size of head. At the sides of this headband opposite the ears, are extended two angular bars graduated in one-half inches. On each bar is a sliding upright piece controlled by a thumbscrew and with a small hook at the top to suspend a watch; the watch will be in the exact line of the external canal. The headband has two eye shields to obstruct patient's vision, for obvious reasons. It is preferred that the watch should hang on a string from the hook, as it will prevent a solid contact of watch with the instrument to transmit vibrations. It is by moving this sliding upright with the watch that gives accurate data of the progress of the case.

103. **Apparatus for Proctoclysis.**—This apparatus consists of a vacuum bottle with a specially fitted brass stopper containing an outlet tube for the fluid and an inlet tube for air extending to the bottom of the bottle. The dropper consists of a glass barrel having an inlet tube with a stop-cock attached and an outlet tube. The most important part of the dropper is the air vent which not only eliminates any tendency toward a vacuum formation which would inhibit the flow, but also permits of the free expulsion of gases from the rectum without in any way contaminating the fluid in the container.

106. **Abdominal and Pelvic Drainage.**—Bonifield uses plain gauze wrapped with a thin layer of iodoform gauze and the large wick thus made is put in a rubber tube long enough to extend from the bottom of the abscess cavity through the abdominal wall. Enough gauze protrudes from the end of the tube to completely fill the abscess cavity. His reasons for using plain gauze wrapped in iodoform gauze are as follows: Iodoform gauze arrests hemorrhage better than plain gauze; it seems to be less irritating to the structures with which it comes in contact; they do not cling to it with the same tenacity, and it remains sweet longer when used in infected areas. This drain is applicable whenever drainage is required in the peritoneal cavity. Its size and length are subject to the widest variations. It is made of materials always to be found in any well-equipped operating-room. It requires little time to properly fashion them and most important of all one drain will in the majority of cases be sufficient to meet all requirements.

Bonifield mentions another method of drainage brought to the attention of the profession by Lawson Tait, but largely forgotten now, namely, free purgation with salts. By such purgation the peritoneum was made to absorb rapidly and take care of a limited amount of infectious fluid without much harm to itself. When other drainage is employed its use is seldom necessary, but when the abdomen has been closed without drainage and there is evidence of a mild infection of the peritoneum, Bonifield says he knows of no more rapid or more sure way of arresting the extension of the inflammatory process than by drainage through the intestinal tract produced by free purgation.

118. **Chronic Ascites.**—McDill's experiments show that the ends of three strands of No. 20 silk, sewed together, slightly projecting into the lower levels of the peritoneal cavity become a permanent silk-connective tissue peg; that the breach it makes in the abdominal wall allows the escape of fluid, and that the hernia liability is nil. The procedure need not confine the patient to bed for more than one day; is not much more formidable than an ordinary paracentesis abdominis, and can be repeated if necessary at any subsequent tapping until there is sufficient drainage. The permanency of any improvement will depend on the internal treatment.

119. **Incontinence of Urine.**—The points involved in Baldy's operation are: To make permanent pressure on the neck of the bladder and the bladder end of the urethra. This is accomplished by bringing the vaginal mucous membrane and the underlying fibrous tissue from side to side so tensely as to make firmer pressure. This is done by making a denudation of the vaginal mucous membrane and the underlying fibrous tissue at the neck of the bladder; and by bringing the edges of the incision together laterally by interrupted sutures of silkworm gut; and finally, by placing a single reinforcing suture with which to take tension off the suture already placed. The denudation is carried one-half to three-quarters of an inch both fore and aft from the neck of the bladder, in order to insure full pressure at the neck.

The denudation is an oval, the widest point of the oval being as near the exact neck as can be calculated, in order to insure most pressure at that point. The width of the denuded oval is limited only by the possibility of bringing the edges forcibly together with the aid of tenacula. This is important, as it is this which gives the pressure. The denudation is carried into, but not through, the underlying fibrous tissues; resection of this tissue is avoided. The object is to double the fibrous tissue on itself and get a deeper and firmer scar than could be gotten by a resection and bringing the comparatively narrow edges together.

The stitches are of fine catgut, interrupted. The first one is placed directly at the neck, in the cenetr of the oval. They are introduced laterally, are brought out at the bottom of the wound and reintroduced to be carried across and out on the opposite side. Care must be taken, however, not to leave a blind space in the depth of the wound. Too much tension cannot be made on the stitches: the width of the denudation had better be overdone than underdone. The idea is to make it as tense at this point as possible in order to make the utmost pressure. After all sutures have been tied the reinforcing suture is placed. The object of this suture is to draw the tissue from side to side of the vagina over the line of sutures already placed, so as to relieve them from tension until healing has occurred. In placing this suture a point well away from the line of sutures directly at the point of greatest tension is chosen so as to make full allowance for the subsequent cutting of this suture. The needle is introduced in the direction of the long axis of the vagina, so as to get abundance of tissue. A quarter of an inch, longitudinal to the line of suture, can be picked up on both sides of the line of sutures. The suture is carried in depth as far as possible without perforating the bladder mucous membrane. In this way a sufficiently large bunch of tissue is included in the grasp of the suture as to insure against cutting out before healing has fully occurred and the parts have adjusted themselves. The subsequent treatment consists in keeping the sutures as clean and dry as possible, and of the use of the catheter several times a day. The sutures are removed at the usual time for plastic work.

121. **Acute Hemorrhagic Pancreatitis.**—The peritoneal exudate in acute hemorrhagic pancreatitis, according to Whipple and Goodpasture, contains no toxic substances. It is harmless when injected intravenously or intraperitoneally in large amounts into normal dogs or those suffering from acute pancreatitis. The ferments which escape from the injured pancreas are rapidly neutralized, and this peritoneal exudate usually is free from proteolytic ferments and contains the same amount of lipase as does the blood-serum. The hemorrhagic peritoneal exudate may be looked on as having a neutralizing action and appears to benefit rather than injure dogs suffering with acute pancreatitis. Dogs with acute hemorrhagic pancreatitis which are subjected to exploration and removal of peritoneal exudate will appear sicker than control dogs left undisturbed. The pancreas can survive remarkable grades of injury, and this factor of safety should always be considered in drawing deductions from any surgical procedure. Its adaptability of repair seems greatest when the gland is left undisturbed in a closed abdomen.

123. **Surgery of Ileocecal Valve.**—The operation which Kellogg performs for insufficient ileocecal valve action does not differ from the ordinary mode of proceduce in end-to-side anastomosis of the small intestine with the colon except in one important particular—that there is a distance of two to three centimeters, measured along the surface of the intestine, between the inner and the outer suture lines. This permits the inverted small intestine to project into the colon about half an inch. The portion of the ileum thus intussuscepted forms a good valve for the reason that the folds of mucous membrane readily fall together whenever there is the slightest backward pressure. In Kellogg's opinion the so-called stort-circuiting operation or ileosigmoidostomy, or any other operation whereby an anastomosis is made between the ileum and the colon, should never be performed without the construction of a valve for the prevention of reflux from the colon into the ileum. Without an ileocolic valve to prevent reflux, an ileosigmoidostomy performed for the purpose of getting rid of the intestinal intoxication arising from stasis in a looped, kindred or otherwise crippled colon may leave the patient in a condition as bad as, or even worse than, before the operation by practically converting into a colon many feet of his small intestine. The best point for attaching the ileum to the colon, Kellogg states, is near the upper end of the distal leg of the pelvic colon. Great care must be taken to avoid bruising or unnecessary handling of the intestine, so as to prevent adhesions, the formation of which about the point of anastomosis may become a source of obstruction.

125. **Irregular Kidney Vessels in Fifty Cadavers.**—Of the fifty cadavers, thirty-five, or 70 per cent., showed a unilateral or a bilateral anomaly of the renal arteries or the veins, or both.

129. *Abstracted in* The Journal, *May 31, p. 1738.*

131. **Preserving Integrity of Potential Body Cavities.**—In order to ascertain whether celloidin could be used to advantage in situations in which adhesions are most apt to form, the brain, joints and nerves were selected by Prime as the most suitable places to introduce the tissue. Within the cranial cavity there would be no adhesions if a piece of celloidin were placed beneath the dura, but between the celloidin and the dura, and often between the celloidin and the brain, a connective tissue membrane would form which was smooth and glistening and free from fibers binding it to the underlying tissue. The same thing was found along the nerves, and even when, as a mass, the celloidin was found wrapped in the omentum, the same glistening membrane was found, with the celloidin quite free within it.

The explanation of these phenomena seems to be that at the time of operation, when, for example, the dura is opened and manipulated, there is sufficient injury done to this delicate membrane to set up a reaction, and cause an exudate to be thrown out. The celloidin present prevents this from reaching the underlying surface, so that when the connective tissue begins to grow into this exudate, it simply grows along the surface of the celloidin and the dura, thickening the latter.

In cases of nerve suturing, the results were most satisfactory. A nerve in the foreleg which had been cut across and sutured with fine silk, and a celloidin tube slipped over the point of suture, at the end of ten days showed no evidence of the nerve being bound down, but was free in the tube, and at the end of six weeks another which had been wrapped with a piece of celloidin tissue showed a sheath of connective tissue which had formed over the celloidin, leaving the nerve healed and free beneath it. In places such as the joints it can be used to prevent the formation of new adhesions or hinder the reformation of old ones.

133. **Endoperitoneal Shortening of Round Ligaments.**—The modification which Schmitz proposes and has already executed in a few cases is as follows: Attach a Barrett ligature carrier to the ligature applied to the distal end and carry it between the layers of the broad ligament to the posterior surface of the uterus underneath its peritoneal covering. Make a very small performation in the center of the peritoneal covering to enable one to catch the ligature and thus hold the ligament in position. The same procedure is now carried out on the opposite side. The two ligatures are tied, uniting the two ends of the round ligaments. The latter are finally secured to the posterior wall of the uterus by a few interrupted fine chromicized catgut stitches. These should only include a portion of the round ligament, to prevent gangrene of the same. Finally the proximal end of the round ligament is attached to the distal end as in the Alfieri modification, and the peritoneal incisions are closed. The round ligament now has the form of a Y. The advantages claimed for Schmitz's modification are: 1. The ligaments remain entirely extraperitoneal. 2. There is a mucomuscular attachment between the uterine mucosa and the denuded round ligament. 3. The method does not use the strongest portion of the round ligament for the shortening, hence the functional ability of this ligament is as nearly normal as possible.

137. **Method of Controlling Hemorrhage in Thyroidectomy.**—The following are the steps of Jones' procedure: The usual transverse collar incision is made, dividing the skin and platysma. The upper flap is freed to the upper border of the thyroid cartilage. Then at a point opposite the middle of the thyroid cartilage the fascia over the vertical muscles is slit in a longtudinal direction a finger's breadth inside the border of the sternomastoid muscle. This slit is extended upward

and downward for a distance of about two inches. With narrow-bladed retractors the fascia of the sternohyoid and the sternomastoid muscle is drawn outward, the sternohyoid and sternothyroid muscles inward. The finger is pushed down through this space until the pulsation of the carotid are felt. By blunt dissection the fascia just to the median side is penetrated when the finger is felt to be in the loose areolar tissue in front of the longus colli muscle. Retractors with longer blades are then substituted. The sternomastoid and carotid sheath are drawn well outward while the vertical muscles and thyroid gland are displaced inward. The space back of the carotid sheath is in this manner well exposed. The carotid tubercle, which is the important landmark, should now be located. About a finger's breadth below the tubercle, the artery is sought for with two pairs of blunt dissecting forceps. It lies in the loose connective tissue and at the extreme point of its arch seems to be surrounded by a sling of rather firm fascia which binds it to the carotid tubercle. When a short area is freed, a ligature may be passed around with an aneurysm needle. The ligature is tied, the retractors removed, and the parts allowed to fall back to their natural places, and the operation of intracapsular thyroidectomy proceeded with in the usual manner.

11. **Gastric Tetany in Adult.**—Irwin has collected the records of thirty-nine instances of the disease. Of this number 24 were males and 15 females. The average age at which the disease appeared was 42, the youngest patient being 20, and the eldest 66. In the great majority of the cases the symptoms of gastric disease had existed for many years prior to the onset of the nervous affection, and in only three instances out of the entire number for a period of less than twelve months. Out of 19 cases in which an accurate account of the post-mortem examination is recorded, 11 exhibited a dilated stomach, due to the contraction of a chronic ulcer in the pyloric region. In one case the pylorus was greatly contracted from the cicatrization of a chronic ulcer, but there was not much dilatation of the stomach; in two cases the gastric dilatation was dependent on the cicatrization of an ulcer in the first portion of the duodenum. In one case cancer of the pylorus coexisted with chronic ulcer, but in another case a large growth, evidently cancer, was found at the pylorus. In only two cases was the increase in the size of the stomach found to depend on simple atony of its walls. From these facts, Irwin says, it is evident that in the majority of these cases dilatation of the stomach was a long-standing affection, and owed its origin to the presence of a chronic ulcer in the pyloric region. In the majority of the cases the nervous symptoms consisted of a tonic contraction of the muscles of the hands, forearms, feet and legs, but in a few, tetanic contraction of the jaw and body muscles were present. In three cases seizures of an epileptiform nature were present. Out of the 39 cases recorded only 11 recovered. Every drug, from calomel to the latest antiseptic, has been tried. Numerous authorities recommend gastric lavage, but this is a rather dangerous procedure, as passing the stomach tube, even a soft one, very often induces a severe attack of tetany. Others have advised the patient to take a large quantity of water, followed by an emetic, but Irwin could not find any case recorded in which this treatment had been successful. The only treatment up to the present that has given hopeful results is operation, but even this has not always prevented a recurrence of this grave disorder. The patient should have a dose of calomel and then a saline purgative every morning. Fifteen ounces of peptonized milk should be given by the rectum every six hours, and the bowel should be kept well cleansed by giving a saline or soap enema once every twelve or twenty-four hours, and about an hour before the rectal feed. Oral sepsis must be avoided by daily washing the mouth and cleansing the teeth and gums. This will also prevent parotitis, at one time a serious complication. In cases in which rectal feeding has been necessary and food by the mouth has been prohibited, the patient should have a rubber teat to suck. By the above method, Irwin claims the attacks become less frequent and less severe, and tend to disappear usually about the third or fourth day of treatment.

12. **Acute Dilatation of Stomach.**—Richardson saw this patient seven hours after the sudden attack. He says there was no difficulty or doubt about the diagnosis, but three features of the case were noted as unusual: 1. The abdomen had not the extreme board-like rigidity generally present in such cases; indeed, for a case of ruptured ulcer, the abdomen was rather lax. 2. There was abdominal respiration and very little movement of the chest-in contrast to the usual fixity of the abdomen in such cases of recent peritonitis. 3. The pupils were widely dilated. The abdomen was opened and the diagnosis was confirmed, a chronic duodenal ulcer about half an inch from the pylorus with a perforation at its center. There was lymph on all the adjacent peritoneum, the stomach was empty and small. The hole in the duodenum was closed with a catgut purse-string suture reinforced by a row of silk sutures. The operation was simple and easy in every way but one. The only trouble arose from the difficulty in administering the anesthetic satisfactorily. Anesthesia was induced with chloroform (he appeared to be an alcoholic man, and he struggled a good deal), and it was kept up with ether, given by the open method, throughout the operation. Richardson had sewn up about two-thirds of the peritoneal wound when he noticed about two-thirds of the upper part of the abdomen was distending. In less than half a minute the stomach was bulging into the lower part of the wound and the distention increased so rapidly that the suture had to be unlaced. The stomach dilated more and more until it became drum-like and very tense. It appeared to be anchored at the pylorus and the cardiac extremities, because, as the distention increased,

it rolled upward, bringing the greater curvature forward. The veins on the stomach became very prominent and enlarged. Richardson did not see any distention of the duodenum, and the lower part of the abdomen did not increase in size. A stomach tube was passed by the mouth, and immediately there was a rush of gas through the tube, and the distention disappeared. The stomach then became firmly contracted and not greater in diameter than a piece of large intestine. The muscular contraction was extreme and there was no peristaltic wave. It contracted in sections, there being alternating white rings and intervening portions more naturally colored. The venous engorgement of the stomach also disappeared entirely. At the same time the respiration became quiet and wholly thoracic, the complexion became pink, the pupils contracted, and the whole aspect of the patient changed. Less than five minutes elapsed between the beginning of the distention and recovery. The patient did well, and did not differ in his after-progress from other cases of ruptured duodenal ulcer.

18. **Micrococci in Blood and Cerebrospinal Fluid in Two Cases of Mania.**—In two cases of toxic insanity a diplococcus was isolated from the blood and cerebrospinal fluid on more than one occasion by Boyd and Brunton. In the one case the organism was Gram-negative, did not grow on gelatin, produced acid and clot in milk, and acid and gas in glucose; in the other the organism was Gram-positive, grew on gelatin but without liquefaction, produced no change in milk, and acid alone from glucose. A number of similar cases showing leukocytosis and other indications of toxemia were examined bacteriologically, but in every case with a negative result.

34. **Blood-Pressures in Pregnancies and Labors.**—Having examined the blood-pressure in cases of albuminuria complicating pregnancy, Donaldson found that the most striking feature is the high systolic pressure in each case. Further, he noticed that in purely toxic cases the pressure tends to fall quickly to normal after delivery. In the question of treatment, the observations on blood-pressure seem to be of some importance. A rising blood-pressure in spite of treatment is considered by Donaldson to be an indication for terminating the pregnancy. Observations of blood-pressure were made also in a case of pernicious vomiting in which labor had to be induced. In this condition the pressure is not raised, a fact that suggests to Donaldson that the toxin in these cases differs from that of albuminuric cases. The blood-pressure estimated in a case of glycosuria complicating pregnancy showed nothing abnormal.

35. **Operation for Carcinoma of Cervix Uteri.**—The authors' 71 operations were chosen from 112 patients with carcinoma of the cervix presenting themselves for treatment over the period April, 1907, to June, 1910—an operability rate of 63 per cent. These 112 cases represent every patient that came under observation. Sixteen patients died of the operation; 20 died of recurrence; 2 died of intercurrent disease; 2 disappeared; 3 are alive, but with recurrence; 28 are alive and well. Ten patients died of shock, 2 died of paretic ileus, 1 of mechanical ileus, 1 of pelvic suppuration and empyema, 1 of post-operative hemorrhage and 1 of bronchopneumonia. The deaths by shock comprise those who succumbed a few hours after the operation, apparently as the result of its severity and in whom no signs indicative of any other cause of death could be found either clinically or on autopsy. In the cases in which the glands proved to be carcinomatous at the operation the mortality was 29.5 per cent. In 23 cases the disease recurred. Three of these patients are still alive at periods of four years or over from the operation. In only one place did the recurrence take place in the vaginal scar. In the rest the growth has appeared either in the upper part of the pelvis or in the situation of the aortic glands. The recurrence rate, therefore, if reckoned on those surviving the operation (55) works out at 41.8 per cent. These figures rest on a three years' basis.

42. **Heredity and Inheritance in Relation to Physician.**—From his observations Mercier summarizes his views as follows: In the first place, if a child is very precocious it is never safe to predict that it will set the Thames on fire. Mercier excludes musical prodigies or calculating prodigies, because music and mathematics, like chess, and linguistics, and certain other faculties, have no relation to general ability. They may be highly developed in the dull, and they may be absent in exceptionally clever men. They go for nothing. In the second place, when a hitherto intelligent child becomes stupid, dull, clumsy and even when it exhibits mental traits that are distinctly abnormal and alarming, we need not be much concerned if we find that it has started into rapid growth; and if the growth is very rapid almost any mental symptom may be witnessed without alarm. In the third place, we need not fear ill results from stimulating the intelligence of a child, even of a precocious child, provided it is healthy in body, eats well, sleeps well, and is not disturbed by dreams, and provided we do not continue the stimulation into the period when bodily growth has started and the development of mind has no backing. The week that the child starts into growth all stimulation of the intellect should cease; and when the growth is rapid intellectual exertion should be restricted and watched with vigilance. Especially if there is in the family any tendency to nervous or mental disorder, children who are growing very rapidly should be withdrawn from school altogether until the period of rapid growth is over. Mercier says that if he had charge of a school he should measure and weigh the children frequently, and should

regulate their intellectual exertion according as growth was active or quiescent. He does not think that intellectual work at high pressure is harmful to either boys or girls as long as food, sleep and bodily exercise are sufficient; but is quite sure that pressure of intellectual work *in those* who are growing rapidly should never be permitted; and if growth is proceeding very rapidly, all intellectual work should be put aside. Another thing which, in his opinion, requires careful regulation is the diet. It is scarcely possible to give growing children too much to eat, and it should always be borne in mind that the carbohydrates—starch, sugar and fat—are mainly fuel that is burnt up in producing muscular movement, and that the proteins are the main elements in the formation of tissue. Consequently, it is a mistake to restrict the meat ration of children.

**43. State of Blood-Vessels in Shock.**—Malcolm is in accord with Henderson, that in cases of fever, of postoperative intestinal obstruction, and of traumatic shock there is a persistent and increasing contraction of the arteries, a conclusion which he believes to be demonstrable at the bedside.

**46. Sensitized Virus Vaccination in Gonorrhea.**—Cruveilhier has not yet come to any final conclusions concerning the various modifications which, in his opinion, ought to be made in Besredka's method of sensitized virus vaccination in order to adapt it to the treatment of gonorrhea. Yet he is able to state that, as has been proved by the experiments of Metchnikoff and Besredka in antityphoid vaccination, it is always preferable to inject living sensitized virus. In a certain number of cases, when Cruveilhier had absolutely failed while persisting in using dead sensitized virus, he obtained excellent results from the use of living sensitized virus. The serum which he employed in his operations was taken from a she-goat to which he had successfully applied Besredka's subintrant injections of the veins in order to render it immune. He considered that it was not advisable to take from the patient himself the gonococci to be sensitized, and he took them from the cultures which he had had in stock for several months. The injections were principally made in the subcutaneous cellular tissue and were repeated at intervals varying according to the different cases. None of the patients showed any sign of severe general reaction. In some cases there was a slight rise of temperature during the hours which followed the injection. Sometimes Cruveilhier also noticed at the site of the injection some erythema accompanied by a pain which never lasted longer than forty-eight hours.

**47. Experiences in Nerve Surgery.**—Brachial plexus lesions, if traumatic, Tubby says, are hopeful, if the loss of power has not existed for years. If due to other causes the outlook is not so good. However, he cautions that we should not despair of a case recovering, even five years after the operation, provided that the improvement has set in within three months after the operation and is continuous. Popliteal neuroplasty for infantile paralysis, he says, has proved disappointing for the reasons given previously. Injuries about the wrist should never be sewn up until the continuity of the nerves has been ascertained, and until all the electrical reactions have been tested. If the lesion of the nerve is compression by a scar the outlook after operation is most hopeful. If the nerve has been severed primary operation is very hopeful, but secondary suture rarely permits a complete recovery. No case, however, of traumatic nerve lesion Tubby would regard as hopeless, in view of the achievements of neuroplasty. Tubby calls attention to a painful condition connected with enlargement of the head of the first metatarsal bone, where there is not only tenderness on the inner side of the joint but also severe pain on its outer side and in the first interdigital space. This is a condition special to those cases in which there is lipping of the joint surfaces and a deposit of osteophytes, and the cause appears to Tubby to be as follows: On dissecting the part there will frequently be found a communicating branch passing from the digital trunk of the anterior tibial nerve to the corresponding nerve on the plantar surface. This communicating branch arises opposite the most prominent part of the head of the bone and passes immediately downward over the capsule of the joint, to which in inflammatory cases it is often adherent, and it joins the digital branch of the internal plantar to the outer side of the great toe. It is easy to see how painful compression may arise, and the remedy Tubby has adopted is simple: i. e, to dissect away the communicating branch and remove the osteophytes.

**62. Means to Reduce Hernia of the Brain.**—Eleven days after extensive injury of the temporal region from a shell, the wound was the seat of extensive suppuration and the young man was in profound stupor most of the time. There was total amaurosis when he sat up; vision returned when he reclined, but there was no vomiting nor stiffness of the neck. After the wound had been attended to, the brain tissue protruded, the hernia as large as a hen's egg. No means proved effectual in keeping the hernia under control until finally Anastassiades improvised a stopper which answered the purpose admirably. A round of sheet lead was bent over a metal cylinder to make a depression in the center just large enough and deep enough to fit into the gap in the skull. This stopper was boiled and applied between two sheets of gauze. The brain tissue was thus reduced and held firmly in place while several holes bored in the lead cap permitted ample drainage. As the lesion healed, smaller and smaller caps were used. In two other battle-field cases this lead device proved equally serviceable; these patients also promptly recovered.

73 *Puerperal Phlebitis. G. Keim.
74 Ruptured Extra-Uterine Pregnancy. G. Potherat.

73. **Puerperal Phlebitis.**—Keim has long affirmed that puerperal phlebitis may occur without infection, merely from the combined effects of the impeded circulation from the pregnant uterus and of intestinal auto-intoxication. The functioning of the intestines is hampered as well as that of the vessels by compression from the enlarged uterus, and the liver suffers also, directly or indirectly. One of the principal functions of the liver, its anticoagulation action, may be seriously impaired, and this invites thrombosis, that is, coagulation and accumulation of sediment at points where the blood-stream is most sluggish or where there are eddies and back currents.

Phlebitis and phlegmasia of purely toxic and mechanical origin simulate infectious affections of the kind, but they relieve the obstetrician and the nurse of direct responsibility for them and are generally inclined to be benign. Much can be done in prophylaxis. The intestines and the liver must be supervised with special care during the pregnancy and the uterus should be completely evacuated after delivery. Equally important are measures to reduce the tendency of the blood to abnormally early and excessive coagulation. He has been gratified with the results of organ therapy for this purpose, giving in an enema 100 gm. of fresh calf liver in emulsion in 250 gm. of water, to which 10 gm. of peptone have been added. This aims to induce an anticoagulation action from the calf liver to supplement the insufficient action in this line of the patient's liver. He regards this as a specific organ therapy, and has never had phlebitis develop in the cases in which the method has been applied and has witnessed the prompt relief of symptoms in cases of already developed phlebitis. Sobre-Casas has also reported equally favorable experiences with this form of opotherapy in puerperal phlebitis. Other means to combat the tendency to excessive coagulation may be useful likewise. During the pregnancy Keim insists on treatment of any intestinal trouble and constipation, especially if there has ever been a case of phlebitis in the family or the patient feels pain in the side, or has ever had signs of liver trouble. He warns that intra-uterine injection of any fluid is liable to induce an actual aseptic metrophlebitis.

76. **Cancer of the Large Intestine Outside of the Rectum.**—Körte devotes nearly ninety pages to analysis of the 254 cases of cancer of the cecum and colon which he has encountered since 1890. The radical operation in eighty-three cases gave a mortality of 62.5 per cent. when the cancer was in the transverse colon and of 45.4 per cent. when located in the descending colon, but the mortality was only 26.4 per cent. when the cancer was at the sigmoid flexure, and only 16.6 per cent. in the thirty cases of cancer in the cecum or ascending colon. He tabulates these experiences in seventeen tables, comparing them with reports from other clinics. The average mortality in all is practically the same, about 30 per cent. The special dangers of cancer in the large intestine are due to the peculiar anatomic conditions and the difficulty of taking care of the contents. He reiterates that with acute obstruction the intestine should be opened in the simplest manner and the growth not removed until later. With chronic stasis and when the nourishment of the stump is defective, it is wiser to operate at more than one sitting. But when the bowel can be thoroughly evacuated and the blood-supply is adequate and the stumps can be united without traction, the resection and suture can be done in one sitting. The prospects for a permanent cure are comparatively favorable with cancer of the large intestine; he has 27.7 per cent. surviving for more than three years in his eighty-three operative cases. In the majority of the permanent cures the cancer was in the sigmoid flexure or ascending colon or cecum. He cites the reports from fifteen clinics, showing 38.3 per cent. surviving over three years, among 434 patients treated by resection; in some the interval since has been up to eighteen years.

77. **Cancer of the Colon.**—Rotter compares his experience in 160 cases with Körte's and gives the details of forty-nine. He classifies the cases according as there was ileus or not. The mortality with ileus is from 70 to 79 per cent., while without it the mortality was only 20 per cent. He emphasizes the advantages of ileotransversostomy for tumors in the right colon; he has had no mortality with this during the last four years, and no mortality at any time from ileosigmoidostomy in the six cases in which conditions called for this technic.

78. **Intracranial Extravasation of Blood.**—Nunberg emphasizes the importance of suspecting rupture of the middle meningeal artery in every case of trauma of the skull, and reports eight cases from the Freiburg clinic which show that an epidural hematoma may develop and even prove fatal from compression of the brain without inducing the typical symptoms. In place of the typical symptoms of pressure on the brain there may be merely vague manifestations which must be regarded as equivalents for the classical symptoms. In some of his own cases the motor restlessness of the patients was striking; this symptom has been noticed by others, and he urges its importance as a sign of injury of the meningeal artery in dubious cases. Other warning signs are transient changes in the pulse-rate, the pulse growing slightly slower or irregular at times. Another important sign that must be sought for is contralateral disturbance of the oculomotor muscles when there is a bruise in the parietal region. An operation to relieve the pressure on the brain should not be deferred to wait for all the signs of pressure on the brain to develop; puncture or exploratory trephining should be considered whenever there are grave manifestations. He adds in conclusion that the puncture or exploratory trephining should be done freely and extensively; a hospital environment is not necessary. In only one of the eight cases he reports was the classic picture presented, and consequently no attempt at operation was made, and seven of the eight patients died. In the other case, which may be regarded as a spontaneous cure, Korsakoff's psychosis developed later. In only one of the cases was the pulse typical of pressure on the brain; in two patients not one of the classical symptoms could be detected.

79. **Scoliosis.**—Schanz's article fills nearly a hundred pages and is accompanied by numerous illustrations; it was read at the recent international congress at London. He says that recovery from ordinary benign scoliosis is the rule under any treatment, without any treatment, or in spite of any treatment, and rachitic scoliosis is also under our control if the patient comes into our hands early enough so that the rachitis can be cured in time. But constitutional scoliosis is another matter. We may succeed in arresting the deforming process but we cannot guarantee that this cure will persist, as the scoliosis is the result of unknown processes inside the body. He thinks we have accomplished in the treatment of scoliosis about all that is possible, and for further progress we must look to pathology. The cause of constitutional scoliosis must be some morbid process severely injuring the bone tissue of the vertebrae and thus reducing their weight-bearing capacity. Of what nature is this process? To call it tardy rachitis does

not answer this question, for the clinical course and the clinical findings of constitutional scoliosis are very different from those of true rachitic scoliosis. As long as we class together habitual scoliosis, the congenital, the static, the paralytic and scoliotic sciatica, we may expect confusion—if you eat chocolate and cheese off the same plate, he remarks, *you will never* know exactly how each tastes.

He is convinced that the school does not bring on scoliosis but rather tends to prevent it by reducing the demands on the spine for certain hours of the day. Vertical handwriting, special desk-seats, reform in dress, and special gymnastic exercises do not banish scoliosis from the schools. We find as many cases of curvature of the spine in schools where all this is done as in those in which nothing of the kind is attempted. In treatment, the indications in the individual cases presented by the developing and the already developed deformity form the most important and most responsible elements for treatment and the most interesting, as each case must be strictly individualized as he shows by illustrated descriptions of the course of a number of cases. He warns that gymnastic exercises are liable to do harm in some cases, and that the benefit apparently realized is a deceptive correction. The courses of special gymnastics for curvature of the spine should be restricted to comparatively strong children and to cases in which the weight-bearing balance has not been too seriously upset.

86 Present Status of Treatment of Cancer. (Behandlung der bösartigen Geschwülste.) F. Blumenthal. Commenced in No. 42.

**82. Chronic Otitis Media.**—Schwabach describes in general the pathology and treatment of chronic disease of the middle ear. He says that even when it is possible to cure the old otorrhea and heal up the perforated membrane, yet generally the hearing is left permanently impaired. More frequent are the cases in which the suppuration seems to be cured but the perforation in the membrane does not close and thus it provides an opening for entrance of infection, bringing back the old trouble. He agrees with Wilde that so long as there is discharge from the ear we can never say how, when and where it will end nor to what it may lead. He gives directions for cleaning out the secretion, and says that Bezold's method frequently cures the old affection and in the simplest way. It aims to cleanse the secreting surface from all sepsis germs and exclude it from new influx of germs from the air. He accomplishes this by injecting a boric-acid solution until the outer passages and tympanum are cleansed. Then after thorough drying with the air douche, he insufflates finely pulverized boric acid and pours more into the outer passages which he then plugs with medicated cotton. This procedure is repeated as often as the cotton is moistened with secretion. Schwabach says that since he has been using this method he has had no need for local astringents, but he warns that it should be done by the physician and never given over to the patient. This method fails of course when there are other complications and he discusses the means to meet these.

**83. Benzol in Cancer.**—Kiralyfi reports two cases of inoperable recurring mammary cancer in a man and a woman, in which he applied benzol, suggested by its action in leukemia. In both cases the cancer tissue was destroyed by the direct contact with the benzol, but the cancer tissue beyond continued its course unmodified. Benzol has evidently a remarkable influence on the cancer cells, but this is merely a local action; there can be no question of a curative influence on the cancer from the benzol. He says that this applies also and in the same way to Roentgen therapy, thorium or any other nonsurgical means of treatment.

87 *Tuberculosis of the Prostate. F. A. Hesse.

**87. Tuberculosis of the Prostate.**—Hesse's analytic and critical study of the literature on this subject fills this entire number of the *Centralblatt.* He classifies the literature alphabetically by the authors—a total of 1,201 titles. The testimony all points to the superiority of operative treatment, radical removal of the focus into sound tissue. Concomitant pulmonary tuberculosis often becomes materially improved when the focus in the prostate has been done away with. Conservative measures may relieve and improve the prostate lesion, but only in the rarest instances is a cure realized without an operation.

**90. Lavage of the Stomach.**—Boas comments on the way in which experience has shown the advisability of restricting the use of the stomach-tube in treatment of chronic stomach affections to a preliminary clearing out of the organ, to start the course of dieting. Repeated lavage of the stomach is not required afterward with mild degrees of stenosis. Once cleared out, there is no further use for the stomach-tube and it merely torments the patient. The stomach will take care of fluid food for a week, and then soft foods can be added, gradually increasing the diet until the tolerance limit is reached, the so-called microretention. This should then be the standard diet, and be kept up for weeks. The case is different with advanced uncontrollable stenosis, but repeated lavage is not necessary even here as the surgeon should be called in without delay. If the patient refuses an operation, the diet should be regulated so that lavage will not deprive the organism of too much nourishment. A combination of purgatives with antiseptic rinsing out of the stomach may be useful, but he never gives the antiseptic until after the stomach has been thoroughly rinsed out. He has found magnesium salicylate the best for the purpose (from what can be taken up on the tip of a knife to a teaspoonful, three times a day). With chronic stagnation from benign and malignant stenosis of the pylorus, simple expression of the stomach content without pouring in a fluid has proved as effectual as lavage in ten years of experience with this measure. The difference between the effect realized is immaterial; patients who have tried both lavage and dry expression always prefer the latter. The technic is simple and easy, the patients requiring no help from without as they readily learn to swallow the tube. He adds that a large number of ingenious apparatus have been invented for autolavage, and illustrated descriptions are given of them in the text-books, but no one seems to use them.

He does not think that it is mere chance that he has had no cases of tetany in the last ten or fifteen years since he has restricted the use of lavage to the above indications. Even with chronic gastritis, the tendency to catarrh is not affected by lavages; this can be controlled far better by suitable diet, mineral waters and avoidance of irritants Benefit from lavage in nervous affections of the stomach is probably the effect of suggestion alone.

91. **Parasites of Variola and Vaccinia.**—Paschen and Paul describe their latest research on the minute bodies which Paschen regards as the causal agent of variola and vaccinia. Paul gives an illustrated description of his apparatus for demonstrating ultramicroscopic forms of virus.

92. **Serodiagnosis of Mental Diseases.**—Fischer reports a further series of eighty-seven patients with dementia praecox, general paresis or epilepsy, tested by the Abderhalden technic for protective ferments. The results confirmed in every case the specific nature of the ferments elaborated in these affections. In the paresis cases, the serum digested cortex tissue but never genital-gland tissue. In the sixteen epileptics, cortex tissue was digested in only one case. In the dementia praecox cases, cortex tissue was digested in the majority of cases, and thyroid tissue in ten of thirty-seven examined, and sexual-gland tissue in fifty-six of fifty-seven examinations. In fifteen cases, both testicle and ovary tissue was tested, with the result that the serum of men digested only testicle tissue, female serum only ovary tissue, and never testicle tissue. Fischer has applied the Abderhalden technic 700 times.

93. **Action of Light on the Human Organism.**—Pincussohn has continued his previously reported research on the action of light after sensitization with eosin or other fluorescent stains. He experimented with dogs, cats, guinea-pigs and rabbits, the results confirming the intensification of the action of light on tissues and organs by this means. It opens a prospect of being able to apply light in therapeutics with more accurate doses and aims than has hitherto been possible, thus magnifying the therapeutic effect of ordinary and artificial light.

103 Dermatology for the General Practitioner. (Dermotherapeutische Winke für den Praktiker.) J. Schäffer.

96. **Treatment of Defects in Speech.**—In the course of this study of what the general practitioner can do to ward off and cure defects in speech, Fröschels emphasizes that much can be done in preventing the development of stuttering. When a child hesitates and repeats the last syllable over and over, it is because its little brain cannot keep up with its speech; it keeps repeating the last syllable until it can think of the proper word to go on with. This is not pathologic, but it becomes so if the child's attention is drawn to this habit. The family and friends must have impressed on them with great emphasis that it is absolutely necessary to refrain from attracting the attention of the child to this slight defect in its speech. It must not be corrected, nor forced to repeat the word over again, and, above all, no impatience should be manifested. If the child's attention is once attracted to this simple repeating of the last syllable the trouble becomes confirmed and we have the severe disturbance of stuttering which may brand the individual through life and make him hold aloof from his kind.

108 *Significance of the Wassermann Reaction in Wet-Nurses. (Bedeutung der Wassermannschen Reaktion bei der Verwendung von Ammen.) P. Wesener.

105. **Salt Fever in Infants.**—Jörgensen reviews the literature that has appeared recently in regard to fever caused by giving salt intravenously as physiologic salt solution or by mouth. He gave injections to thirty-two children and concludes from this experience that this fever is caused, not by the salt, but by the bacterial content of the water. When the solution was made with freshly distilled water there was no salt fever. This is of considerable practical importance as physiologic salt solution is so frequently given as a stimulant in various diseases. As to its administration by the mouth, it has always been given by previous experimenters in very large doses. In such doses it increases the permeability of the intestinal wall to all substances, and the fever may have been due to increased absorption of other products from the intestine, including some possibly of bacterial origin.

106. **The Sympathetic Nervous System in Infant's Diseases.**—Tezner has frequently observed in very sick infants an injection of the vessels of the conjunctiva, and necropsy has revealed congestion in all the vessels of the head. This he believes is due to decreased tone of the cranial sympathetic nervous system. This appears only in the severe acute intestinal intoxications. It is never present in chronic intestinal disturbances. Prematurely born infants have a greater tendency to atony of the sympathetic during their first three months than children born at term. This lack of tone in the sympathetic system indicates a grave prognosis.

108. **Significance of the Wassermann Reaction in Wet-Nurses.**—Wesener concludes that a negative or weakly positive Wassermann reaction must not be taken as deciding the question for or against allowing a woman to nurse a non-syphilitic child. The decision must be based on the clinical symptoms, etc., as well.

118 The Artist and the Physician. (Die Hohe Schule für Aerzte und Kranke. VIII.) M. Nassauer.

109. **Specific Structure of the Cells.**—Abderhalden shows that it need not be regarded as so wildly improbable that the building-stones of the different organic compounds may be arranged in a specific manner for each organism. Untold billions of combinations of specific building-stones must exist if each kind of cell is to be credited with its individual protein, demonstrable by biologic tests. We know about twenty of these different building-stones, the amino-acids, and we meet ever the same amino-acids throughout nature. He shows by mathematical computations the exact figure of possible combinations of even twenty different amino-acids; it is in the quintillions. Consequently, the assumption that every kind of cell has a special structure, characteristic for itself alone, is well within the possibilities. Comparative research has shown that cells which have the same tasks in the different individuals of the animal species have certain points of similarity in their structure. The assumption is therefore possible that besides their entirely specific individual structure, certain groups inside the cell exist which control certain functions. Throughout the whole animal series the organs

on which certain tasks devolve, alike through the animal series, all possess certain protein substances which are alike in all. This is evident from the fact that serum which contains protective ferments against a certain organ tissue digests this tissue, not only when it is derived from an animal of the same species, but it also digests the corresponding cell protein of entirely different species. For example, in the serodiagnosis of pregnancy the placenta of one animal can be used for other kinds of animals. He calls this a new biologic law and emphasizes its practical importance as it permits the organs of different animals to be used in clinical biologic tests. He remarks that while everything else in the cell may be different, yet one single protein may be identical and this gives the characteristic response. He compares it to the way in which a musician can detect the sound of different instruments in orchestral music while the unpracticed ear hears only the music as a whole.

112. **Salvarsan in Syphilis.**—Berger combines salvarsan and mercury inunctions and here reviews his experience in a military hospital and recent reexamination of numbers of patients from 16 to 22 months afterward. Although he regards it as almost certain to abort the disease yet he insists on chronic intermittent treatment for five years. If the Wassermann reaction is repeatedly negative, he gives mercurial treatment alone, but if it can be made positive he interposes a supplementary course of salvarsan during the second year. About three-fifths of all syphilitics can count on a permanent serologic cure. Disagreeable sensations in the gums were observed in a few cases, a bitter taste in the mouth, pulsation in the gums, and he warns that when the gums feel hot and prickle the salvarsan should be suspended. These sensations in the gums in one case preceded by two days a fatal encephalitis after salvarsan. In one case an almost somnambulistic condition followed the salvarsan. No secondary symptoms or positive Wassermann were found in any of the patients followed to date since 1910-11 who were given treatment in the primary stages. All but one have been free from recurrence among the thirty-six in the secondary stage. Negative Wassermann dropped from 70.4 per cent. to 61 per cent. in those with secondary syphilis one year after infection, and from 77.5 per cent. to 58 per cent. in those in the secondary stage two, three or more years after infection.

113. **Camphor in Pneumonia.**—Leo was able to protect numbers of mice against pneumococcus infection by subcutaneous injection of a saturated aqueous solution of camphor; the results were less constant with rabbits. These experiences suggest that camphor should be given systematically from the start in pneumonia. He thinks it is able to kill the pneumococci in the blood stream and promote reabsorption of the pneumonic exudate. Camphor has also a marked action in increasing the ventilation of the lungs, the amount of air inspired being very much larger under the influence of the camphor, while the drug stimulates the action of the heart and more blood is thus pumped into the lungs. As twitching was noticed in the animals with a dose of 5 c. c. per kilogram of body weight, smaller proportional doses must be used in the clinic, about 150 or 200 c. c. for a weight of 145 pounds. This represents 0.142 gm. of camphor as each 100 c. c. of the saturated aqueous solution contains 0.21—0.28 gm. camphor. He prefers Ringer's fluid instead of plain water for the vehicle. He quotes Lenzmann to show that 75 c.c. corresponding to 0.1 gm. camphor, can be injected intravenously without disturbance. Lenzmann is soon to publish a report of his experience in this line. Boehncke has already reported favorable experience with camphor plus pneumococcus serum.

116. **Prolapse of the Rectum in Children.**—Lengnick calls attention to the excellent results he obtained in a recent case by drawing up the passage above the anus by means of a strip of fascia taken from the child's own thigh, similar to Thiersch's ring technic.

126 The Cutaneous Tuberculin Reaction Is Specific. (Zur Frage der Spezifität der cutanen Tuberkulinreaktion nach v. Pirquet.) M. Kasahara.

123. **Stenosis of the Pylorus in Infants.**—Ibrahim's figures for the mortality from stenosis of the pylorus in infants are 46 per cent. for those treated medically and 54 per cent. of those operated on. Hess describes two cases operated on by a method devised by Ramstedt, which consists simply in cutting the pyloric ring sagittal to the intestine leaving the mucous membrane intact. The abdomen is then closed. The operation is so much simpler and shorter than any other that it offers hope of reducing the high mortality in this condition.

124. **Specific Nephritis in Congenital Syphilis.**—Hintzelmann accepts the existence of a specific chronic nephritis due to hereditary syphilis. He examined forty-one persons in the secondary stage and found that fourteen of them had nephritis. He gives the case-histories of these fourteen. Other causes for the nephritis were excluded. In twenty-eight tertiary cases examined, only three of the patients had nephritis. In two of these the nephritis was probably due to inunction treatment with mercury which sometimes causes symptoms of nephritis. He states that internal administration of mercury never seems to cause nephritis.

132 Case of Rupture of the Uterus during Delivery Traced to Gonorrhea. A. Solowij.

131. **Resection of the Promontory to Enlarge Contracted Pelvis.**—Schmid and Rotter both conceived the idea about the same time that it might prove possible to enlarge permanently a contracted pelvis by cutting a slice off the projecting promontory, and Schmid has performed the operation on eight women. One of them has since passed through another pregnancy and he here reports the case in detail. It confirms the assumption that it is possible in this way to reduce the projection of the promontory by 2 cm. and permit delivery of a living child by the natural passages. As a rule, the operation is done supplementary to the classic cesarean section, and consequently it can be applied only when there is no suspicion of infection. A tendency to sciatica for a time was noted in one of the patients but it proved transient, and in none of the eight women was there any disturbance in the gait or pain in standing, walking or stooping over. The fear that callus would develop and annul the effect of the operation has proved groundless. At the operation the uterus is drawn forward and pushed up; the posterior sheet of the peritoneum is incised for 10 cm., and the assistant holds the wound open and the sigmoid flexure out of the way; no instrument proved so convenient for this as the fingers in his experience.

### Gazzetta degli Ospedali e delle Cliniche, Milan

135 *Extreme Rarity of Recovery from Sleeping Sickness. (Sulla guaribilita della tripanosi o malattia del sonno.) V. Grossule.

133. **Tuberculous Diaphysitis.**—As primary tuberculous processes so seldom start in the shaft of a long bone, Ruffo suspected syphilis in the apparently healthy man when the left tibia began to bulge in two places, with a dull pain in the region whenever the leg was used much. A vigorous course of mercury caused slight transient improvement—probably from the incidental resting of the leg—but then the process continued to progress in the poorly nourished patient. The limb was never tender on moderate pressure, and there was no fever. Roentgen examination showed in the middle third of the tibia the bone rarefied at two adjacent protruding points on the front of the bone. Recovery was soon complete after excision of the foci. Tuberculosis generally avoids tissues that are extremely vascular or extremely non-vascular; Küttner in 2,100 cases of tuberculous processes in bone encountered only six in which the primary location was in the shaft of a long bone.

134. **Epinephrin and Abortion.**—Silvestri remarks that recent reports in the literature of the benefit from epinephrin in osteomalacia, in uncontrollable vomiting and other disturbances in pregnant women, led him to give epinephrin in such cases, as all the writers emphasized the harmlessness of this treatment in the dosage advised. Two recent experiences, however, tend to contradict the assumption of the harmlessness of this treatment: Two women in the second month of pregnancy were given a mild course of epinephrin and calcium salts on account of an incipient apical process and defective nutrition. Each aborted in less than a month. He has given this treatment to other women in later months of pregnancy and never before witnessed any tendency to abortion. One of the present patients had taken it without disturbance during the last three months of a preceding pregnancy.

135. **Sleeping Sickness.**—Grossule writes from the Belgian Congo district that persons who have apparently recovered from sleeping sickness are liable still to harbor the parasites when reexamined years later. In one such case no trace of them could be found two years after treatment but reexamination two years later disclosed a few trypanosomes in the blood and the cerebrospinal fluid although the man has shown no symptoms at any time since his supposed recovery. Only 100 survived to leave the hospital of the 1,100 patients in his charge, and only thirty-eight of these were clinically cured. In this group fifteen have already shown signs of returning trouble and he is convinced that it is only a question of time when the disease will rouse anew from its long latent stage in the others.

141 *Salomon-Saxl Urine Sulphur Test for Cancer. M. Pasetti.
142 *Technic for Meiostagmin Test for Cancer. G. Di Quattro.
143 *Pararenal Tumors. V. Saviozzi.

136. **Etiology of Cancers.**—Roncali sums up his extensive research and review of the research of others in the statement that the evidence to date seems to indicate that several parasites and consequently several toxins are involved in the causation of cancer. The blastomycetes and their toxins represent only one of the numerous etiologic factors concerned.

137. **Cancer and Fever.**—Giordano tabulates the details of a hundred cases of cancer in which the temperature was studied; fever was evident in 60 per cent. for which no explanation could be found except the cancer itself. In some cases the temperature began to go up in the evening, accompanied by severe headache, and in the course of the night, the temperature dropped, with profuse sweating, and in the morning was a trifle below normal. In other cases the temperature kept high for a week or so, with an intermittent type of fever. In still others the temperature kept throughout of an intermittent type; this was most common with sarcoma; in one case of epithelioma of the uterus the temperature fluctuated according to the quartan fever type. In the majority of cases, however, when the temperature was above normal it kept at an even figure. This continuous type of fever may mislead in the diagnosis unless physicians bear in mind always the possibility of a continuous high temperature in the prodromal period and during the course of malignant disease.

140. **Autolysates of Embryonal, Fetal and Cancer Tissues in Treatment of Cancer.**—Fichera here gives the history of the evolution of the theory on which he bases his treatment of malignant disease. (It was described fully in The Journal, Aug. 6, 1910, p. 545, and June 10, 1911, p. 1769, and the technic was given Jan. 18, 1913, p. 228.) He states that evidence is constantly accumulating to sustain the assumption that the cause of malignant disease is a loss of balance between the chemical and morphologic factors of growth, and that the balance can be restored by supplying from without certain constituents or derivates of the cells—the histogenous therapy of malignant disease. Blumenthal, Lewin and Pinkuss have reported favorable results from treatment along these lines, and many others have confirmed the action of autolysates of normal or cancerous tissues in inducing involution of experimental and clinical cancers. Fichera emphasizes that this histotherapy or histogenous chemotherapy is based on a different principle from that of vaccination; among other reasons, on account of the fact that the latter presupposes parasitic origin, while Fichera declares that there is no conclusive evidence to date incriminating parasites in the origin of cancer. On the contrary, everything tends to prove that certain organs have a tumor-destroying property. In the healthy, the immune and the cured, these organs are well developed and active; in the aged, the cachectic and those with advanced tumors, these organs are shriveled and inactive. Fichera and his coworkers have demonstrated this, they think, by their study of the organs of persons with cancer at different stages; by direct grafts in different organs; by the property of immunizing and curing and the degree of this property manifested by extracts of various organs and tissues, normal or pathologic; by the effect of removal of the single organs on the susceptibility or resisting power of the animal to cancer, and on the changes in the tumor-destroying power of the serum of healthy animals injected with the tissue extracts.

141. **The Salomon-Saxl Urine Sulphur Test for Cancer.**—Pasetti applied the Salomon-Saxl technic in 200 cases, including 46 cancer cases, 35 of surgical tuberculosis, 92 of other surgical affections, and 27 with syphilis, giving a positive Wassermann reaction. He tabulates the details of them all. Among the syphilitics the response was constantly negative except that 2 gave a dubious reaction; in surgical tuberculosis the response was negative in over 88 per cent. and in over 89 per cent. of the 48 patients with hernia, while the reaction was constantly positive in 68.7 per cent. of the carcinoma patients and in 35.7 per cent. of the sarcoma cases. The test is so simple and easy, he says, and the findings are so frequently positive in case of cancer and negative in its absence, that the reaction merits high consideration in differentiation of malignant disease. (The technic for it was described in detail in The Journal, May 27, 1911, p. 1593.) Pasetti uses

a sedimentation glass with the tapering tip graduated in millimeters for estimation of the amount of the brownish sulphate of barium sediment thrown down. This represents the neutral sulphur in the urine which has been oxidized by the strong hydrogen dioxid, and he leaves the glass for twelve or fourteen hours before final estimation of the amount of sediment.

142. **Technic for the Meiostagmin Reaction.**—Di Quattro says that the livers of certain birds, rabbits, cats and other small animals may be used as the antigen in the meiostagmin test in place of the extracts of human pancreas or of cancer tissue hitherto deemed necessary.

143. **Pararenal Tumors.**—Saviozzi applies this term to tumors which originate in the fibrous or adipose capsule of the kidney and not in the kidney tissue proper. He has found records in the literature of eighty-two cases of the kind and tabulates them for comparison. In none was the correct diagnosis made beforehand. As a rule the tumor develops without pain, merely the discomfort from the encroaching growth until pains come on late. In some cases, however, pain is the first sign of trouble. In the personal case reported the patient, a woman of 57 had complained for a year and a half of penetrating pains in the right lower quadrant of the abdomen; then the tumefaction was discovered, but the operation did not follow until three years after the first sign of trouble. In only thirteen other cases were pains the initial symptom. The urine was normal throughout except in Lothheissen's and in Ranzi's cases in which the tumor had compressed the ureter and caused intermittent hydronephrosis. Compression of the bladder induced bladder symptoms in some cases; pollakiuria or retention of urine was noted in the last four months in Saviozzi's case. The legs frequently showed edema and ascites developed in a few rare cases. Two of the patients had fever and there was slight continuous fever in Saviozzi's patient, but it disappeared at once after the operation. Fluctuation was noted in eight of the cases but exploratory puncture failed to reveal fluid. The fluctuation generally led to assumption of an ovarian or echinococcus cyst. In the 69 operative cases nephrectomy was applied in 38 and the kidney was left intact in 12; there were 21 cases with a fatal outcome and 32 recoveries; recurrence is known in 3 cases and in 13 cases the final outcome is not known. The fatality in several cases was due to hemorrhage during or soon after the operation, and in Kümmel's case to hemorrhage the second day from injury of the spleen. In seven cases the conditions found at the operation forbade the complete removal of the tumor. The article is accompanied by three colored plates showing the findings in Saviozzi's case.

149 *General Paresis in Boy of 10. A. Collett.

150 *Spontaneous Recovery of Renal Tuberculosis. (Kan nyretuberkulosen helbredes spontant?) F. Harbitz.

151 *Hodgkin's Disease. (Om malign lymfogranulomatose.) K. Motzfeldt.

149. **Juvenile General Paralysis.**—Collett gives two colored plates of the findings in the brain of a boy of 11 who had succumbed to general paralysis evidently the effect of inherited syphilis. The child had developed normally and was bright for his age until he was 7 years old. Then an operation was done on the lacrimal sac under general anesthesia, and almost at once afterward the boy's entire character and mentality changed and later the symptoms of general paralysis gradually developed with pupil phenomena and exaggerated reflexes, but no signs of focal disturbances. In connection with this case Collett reviews the literature on the subject of progressive paresis in children. Over 250 cases are on record and in 160 in which the details are known, inherited syphilis was certain in 105, probable in an additional twenty-five, possible in twenty and acquired syphilis was certain in ten instances. Puberty, the puerperium, trauma, masturbation or infectious diseases are stated to have been contributing factors in a number. His own case teaches the necessity of caution in administering a general anesthetic to a child with possibly an inherited syphilitic taint. A history of abortions preceding or following the birth of the child in question should be a special warning. The symptoms and course in children are about the same as in adults, but the pupils are more liable to be dilated rather than contracted. No treatment seems to do any good, he remarks; mercury does direct harm.

150. **Spontaneous Healing of Renal Tuberculosis.**—In routine necropsy work during the last few years, Harbitz found signs of an old tuberculous process in a kidney in twelve cadavers; it had evidently run its course and become encapsulated spontaneously, with what amounted to a clinical cure. In some of the cases the renal tuberculosis had existed for four, six, eight or ten years, and even twenty years in one instance. The processes were of all kinds from the ulcerative to the "sclerosing." In six of the cases the chronic process had become completely encapsulated and the pelvis and ureter were entirely obstructed. Of special interest is the finding that a tuberculous process in the bladder had evidently healed completely after the kidney lesion above had been thus walled off. The data presented reaffirm the rarity of primary tuberculous lesions in the bladder; also that the bladder becomes affected comparatively late in the course of renal tuberculosis, and also that the bladder process generally heals when the kidney process is removed or encapsulated.

In one of the cases reported the tuberculous lesion in the kidney had perforated outward, and yet the whole had healed spontaneously and the fistula closed. In four of the cases the kidney process had not caused appreciable clinical symptoms or merely slight transient manifestations. A tuberculous focus in the kidney is a constant menace to the rest of the organism; two of the patients succumbed to secondary meningitis or miliary tuberculosis, and three to nephritis in the other kidney. Another point brought out by this material is that congenital malformations or displacement of the kidney seem to play an important part in inviting the development of a tuberculous process in a kidney. This was evident in three of the above cases.

151. **Hodgkin's Disease.**—Motzfeldt gives an illustrated description of a number of his ten cases of malignant lymphogranulomatosis, and compares them with similar cases on record. He regards it as a clinical entity, saying that there is no evidence that connects it with tuberculosis, not even with attenuated tubercle bacilli or their toxins or Much's granula. The testimony to date shows that it resembles most the infectious granuloma, but it does not seem to be of the nature of a neoplasm, although a malignant nature seems evident. A transition to leukemia or sarcoma has never been observed. The ages of his patients ranged from 8 to 57.

# THE SCIENTIFIC BASIS FOR VACCINE THERAPY *

RICHARD M. PEARCE, M.D.
PHILADELPHIA

As a justification for any method of treatment, especially if the method is novel and all-inclusive in the field of proposed application, it is essential that those who apply the method should be convinced that it is based on adequate experience. This basis may be that established by the statistical method of clinical medicine, or it may be that of definite experimentation leading to logical clinical application.

By the statistical method of clinical medicine is meant the study by many physicians of the efficacy of a certain form of treatment as applied to a great number of persons suffering from the same disease. Though we describe treatment so based as empiric in method, such description does not necessarily minimize the importance of the method of treatment or of study on which it is based. Too many remedial agents, though introduced at first in curious and diverse ways, have stood the test of the statistical method to justify the position that clinical experience is not an adequate test. The method, however, is a slow one. Its success is dependent on so many details that not infrequently, in the case of a method which attracts such wide attention as has vaccine therapy, the results are as apt to be contradictory through lack of uniformity in method as they are to be exaggerated through the enthusiasm of the individual.

In the field of vaccine therapy, as practiced in this country to-day, it cannot be denied that this contradiction exists and that opinions of the greatest diversity may be obtained. On the one hand, the enthusiasm of its advocates has no limit, and on the other, even among thoughtful physicians, there are few who, while conscious of the exaggerations of the scope of application and the results of vaccine therapy, are not in doubt concerning their duty in the use of the method. These turn to the second guide to rational therapy—the experience gained by laboratory and allied experimentation—and ask what definite scientific basis we have to rest on while we wait for the verdict of the slower statistical method of clinical medicine. But here the laboratory hesitates, and with some embarrassment urges only caution. It can point with pride to the scientific basis for prophylactic vaccination, but has little to offer in the way of support of therapeutic vaccination either as to its efficacy or as to its harmfulness.

The history of small-pox inoculation and vaccination affords an interesting combination of clinical observation—both statistical and experimental—in the establishment of the first known form of prophylactic vaccination. Later Pasteur's experimental demonstration of the principle that a weakened virus (anthrax, chicken-cholera) capable of producing the disease in a mild form renders the host immune from future infection supported the common popular experience concerning naturally acquired immunity, and also the experience with small-pox.

In more recent years the successful use of vaccination against typhoid fever has offered an excellent demonstration of the value of prophylactic vaccination. The principle of prophylactic vaccination is sound, since it agrees with the knowledge concerning acquired immunity based on the clinical (statistical) method as well as the method of the laboratory based on animal experimentation, and, moreover, in its practical application has been confirmed again and again by the statistical method of the clinic.

Concerning the scientific basis for prophylactic vaccination in the fields of its successful application there can be no question. To fortify an animal against a specific infection by producing, in mild form, the disease in question is a procedure against which no objection, scientific or ethical, can be raised. Quite different is the situation in regard to therapeutic vaccination, a procedure which, despite the fact that the idea originated with Pasteur and has therefore as a principle the support of which Pasteur's name and work offer, it is difficult to reconcile with many of the principles of immunity. But Pasteur's idea was not quite analogous to that on which modern indiscriminate vaccination is based. His antirabic vaccination was, it is true, a treatment after infection, but not after the development of the disease. The object was to develop rapidly an immunity after the individual has been bitten in the hope of preventing the full development of the disease—not the cure of the disease after it has developed.

The present wide-spread use of vaccines dates back only to 1902 and to A. E. Wright's advocacy of the use of dead bacteria in various chronic infections caused by these bacteria. At first the method was considered applicable only to chronic infections and for the most part to circumscribed lesions. Now, however, in the hands of its later enthusiastic advocates, it is applied to practically every form of bacterial infection, whether acute or chronic, local or disseminated.

It is possible, therefore, to trace the development of the theory of vaccination through three stages: (1) The principle of prophylaxis, that is, the production of immunity through the development of a disease in a mild form (small-pox, anthrax, chicken-cholera, typhoid fever); (2) the rapid production of immunity after infection, but before the disease manifests itself by its peculiar symptoms (Pasteur's antirabic vaccination), and (3) curative vaccination, or vaccination after the

---

* An amplification of a short communication prepared for the meeting of the Medical Society of the State of Pennsylvania, held at Philadelphia, Sept. 22-25, 1913, but not read.

disease is established and has produced its local anatomic lesions and the attendant physiologic disturbance which we call symptoms.

Concerning the scientific basis of the first and second of these principles, no question arises; only the third is in doubt. Unfortunately for purposes of exact exposition, the clinical extension of vaccination has been so all-embracing, so many diseases have been attacked in a hit-or-miss way, that experimental investigation with its slow and time-consuming methods, so necessary for exact interpretation and conclusive opinion, have not kept pace with empiric practice, and indeed it is doubtful if experimental medicine can adequately study these problems. As Theobald Smith[1] has pointed out, most of the types of disease (typhoid fever, pneumonia, puerperal sepsis, general streptococcus infection, gonorrheal metastasis, and the like) are not exactly reproducible in the laboratory. Moreover, the natural occurrence of local lesions in animals is rare, and their experimental production is followed rapidly by spontaneous healing. These two important types of disease—the one with general dissemination of the causative agent through the blood and the other the purely localized lesion—which are treated at present by the clinical vaccinator are, therefore, difficult of study by the methods of experimental medicine. So also is it with the question of vaccination of typhoid carriers. A typhoid cholecystitis artificially induced in the rabbit in an attempt to reproduce the condition of the human carrier is hardly a real analogy, for the rabbit is not peculiarly susceptible to typhoid infection, and the apparent effect of vaccination would be more conclusive if the infection were induced with an organism to which the rabbit had a normal susceptibility.

The difficulty of reproducing certain bacterial diseases in animals, and the failure of these diseases to follow their course as seen in man, as well as their tendency toward spontaneous cure, minimizes the possibility of utilizing this phase of laboratory method as a means of establishing the efficacy of vaccine therapy in diseases of prolonged course. In acute septicemic disease due to virulent organisms, with early death or rapid recovery as the two possibilities, the experimental method offers some promise, but such diseases are not those amenable to vaccine treatment.

It is through studies based on the latter type of experimental disease that our present extensive, but not at all conclusive, knowledge of infection and immunity is based. It is only in an indirect way, however, that this knowledge can be applied to vaccine therapy. It may be argued that as the line between health and disease is defined clinically with difficulty, so the principles underlying prophylactic immunity may be merged one into the other (Smith). Thus we may harbor disease germs, as the pneumococcus, with perhaps slight infection or slight intoxication, without being aware of it clinically. So also while we speak of antirabic vaccination after infection as prophylactic, it is difficult to say on account of lack of knowledge of the pathology of this disease where the prophylaxis ends and the curative effect begins.

The enthusiastic supporters of curative vaccination stretch this possible application to cover all forms of vaccine treatment and assert that the introduction of large numbers of extraneous bacteria stimulate the natural immunizing process to greater activity, thus artificially fostering the slow process of naturally acquired immunity. For this extension of exact knowledge to cover more than certain localized or slowly developing infections there is no basis in fact. Such enthusiasts lose sight of the fact that there is no common mechanism of immunization. The process differs not only according to the type of infecting organism but also according to its virulence and the localization of its toxin in the host; also variations in the reaction of the infected host play an important part.

No more important principle has resulted from immunologic studies than that the process of immunity in each infection must be studied by itself. The principles of immunity to one infection or poison cannot be applied to another, even if both are due to organisms apparently elaborating their poisons in the same way. For example, compare the difference in action of the specific serums for two organisms—the diphtheria bacillus and the tetanus bacillus—each of which produces a soluble toxin. One is curative, the other at best prophylactic. If this difference occurs in the serum therapy of diseases produced by soluble toxins, and our knowledge of these is perhaps the most satisfactory, how unwise it is to apply a general rule to vaccine therapy, our scientific knowledge of which is so slight.

Is it logical to apply the same procedure to a definitely localized lesion such as the staphylococcus abscess and also to a bacteriemia such as that due to the streptococcus or pneumococcus? Immunology has taught us that many cooperating and interacting forces are concerned, as antitoxins, bacteriolysins, opsonins, agglutinins and phagocytosis. Not all cooperate equally; in one disease, antitoxin formation appears to be the essential mechanism, in another phagocytosis, in a third bacteriolysin, and so on. In no two diseases is the interaction the same, and the reaction may vary according to the individual characteristics of the infected individual. These factors were emphasized by Wright, but are seldom considered by the present-day clinical vaccinator, who applies the same method to all infections. They are, however, the factors on which the scientific basis of vaccine therapy, if it is to be attained, must rest. As many of the known diseases cannot be exactly reproduced in animals, and as reactions vary in different hosts (species), the scientific basis of vaccine therapy can be obtained only through the careful studies of clinical research controlled by the accurate methods of the experimental laboratory. As Smith[2] stated some years ago, "The practicing physician in cooperation with the clinical laboratory will have to work out his own salvation, and this can be done only with the aid of the most rigorous and painstaking methods which medical science can supply. Any other course is certain to lead astray."

The discussion of curative vaccination may be simplified by dividing infections into two groups, the localized and the disseminated. In the case of localized chronic infections, a plausible explanation is at hand and it is this which probably elucidates the frequent successful use of vaccines in this group and fully justifies their use.

A chronic localized infection is probably such because the infected individual has a degree of resistance sufficient to prevent the spreading of the infection. This localization may operate, through a walling off by new tissue and therefore imperfect exchange of fluids, to prevent the entrance in adequate amounts of immune bodies from the blood and lymph, or the bacteria may have become resistant to the mild attack of diluted immune bodies. Surgical intervention may overcome this by allowing, through incision, the escape of easily evacuated contents and the destruction of the infecting agent by the immune elements in the large amounts of fresh blood or lymph which enter the area of infection. Also the dissemination of the bacteria locally may aid to increase antibody formation. Vaccine therapy substitutes for surgical intervention the injection of large numbers of dead bacteria in locations from which their immunity-stimulating substance or substances may be readily absorbed. These acting as a stimulus cause the formation of antibodies, which, entering the blood-stream, rapidly raise the content of immune substances in the body fluids, and these in turn coming in contact with the local lesion, and disturbing the equilibrium between the bacteria and the local reaction, may lead to the overwhelming of the infecting agent.

[1] Smith, Theobald: An Attempt to Interpret Present-Day Uses of Vaccine, The Journal A. M. A., May 24, 1913, p. 1591.

[2] Smith, Theobald: What is the Experimental Basis for Vaccine Therapy? Read at the Annual Meeting of the Massachusetts Medical Society, June 8, 1910.

This theory is supported by our knowledge of leukocytosis—the hyperleukocytosis of an acute non-encapsulated lesion and the normal or hypoleukocytosis of a chronic *localized lesion*. In the latter circumstance substances stimulating leukocytosis do not escape, and the reacting mechanism in the bone-marrow is not stimulated. The condition is analogous to the failure of increased immunity under the same circumstance; indeed, it is difficult to deny that the mechanism of leukocytosis is not perhaps the most important mechanism of the immunizing process in disease characterized by local suppuration. As a practical rule one would expect the administration of vaccine to be of value in local suppuration with a normal or hypoleukocytosis and to be superfluous in that with hyperleukocytosis. This question has been studied in connection with Wright's opsonin index, but in later years, with the increasing doubt concerning the value of this index, the interesting problems of leukocytosis in connection with vaccine therapy have been largely neglected by the clinical vaccinator.

In the second group of infections, those characterized by general dissemination and invasion of the blood-stream, the situation is entirely different, and for curative vaccination no scientific basis, as the result of experimental investigation, can be offered. We know that toxemia and fever are the natural results of bacterial activity and, moreover, that the presence of the former in some degree is essential to the initiation of the immunizing process, and that under experimental conditions this process occurs more rapidly at temperature above the normal than it does at normal temperature. It is difficult therefore to understand how the immunizing process can be hastened, if severe toxemia and hyperpyrexia are already present, by increasing the intoxication by the artificial introduction of more toxin. The argument used to support the treatment of local infections cannot be used here, for in a general septicemia, with organisms in every tissue of the body, the addition of a few million organisms more or less cannot be a factor of great importance; moreover, with such wide dissemination of the infecting agent it would seem impossible, by injection, to bring into action new cell territories, not already involved, for the local production of immune bodies.

It is theoretically possible, on the other hand, in those cases of parasitism—the carriers—in which the toxicity of the persisting organism is of low degree and produces slight clinical symptoms (no fever and no toxemia to stimulate a higher grade of immunity) that the introduction of dead bacteria, capable of being immediately utilized, stimulates the higher level of immunity necessary for the termination of the parasitism. In such cases, vaccine therapy, in that the mechanism of increasing immunity is analogous to that in local infections, would appear to be of value; practically, the treatment of typhoid carriers by vaccination has been an absolute failure.

This summary indicates that we have at least a plausible theory on which to base the practice of vaccination in localized chronic infection; a possible extension of the same theory to carriers, but no experimental or other scientific basis for vaccination in diseases characterized by wide dissemination and general infection.

It is not a part of this discussion to take up seriatim the use of vaccines in the various infections. Certain practical phases of the present use of vaccines must, however, be considered.

### AUTOGENOUS VACCINES VERSUS MIXED VACCINES

In all the early work curative vaccination was based on the principle of making a vaccine from the organism responsible for the lesion of the person to be treated. In this early work the bacteriologist was therefore an important agent, not only in the isolation of the organism, but likewise in the preparation of the vaccine. The field was as a result largely occupied by expert bacteriologists or those specially trained to the needed technic. It is probably for this reason that such excellent results were obtained, especially in the treatment of local infections, to which the procedure was at first limited. Later it was considered justifiable to prepare a vaccine for each of two associated organisms, but still the principle of "autogenous" vaccines held and the vaccines were always prepared from the lesion to be treated. Still later, with the commercialization of vaccines, not only was the principle of autogenous vaccine largely abandoned, but three, four or half a dozen organisms were included in one mixture, thus inaugurating a bacterial polypharmacy, if the term may be used, as absurd and unscientific as the "shotgun" prescribing of our older drug therapeutics. A mixed vaccine for common "cold" containing seven micro-organisms (staphylococcus, streptococcus, pneumococcus, *Micrococcus catarrhalis* group, bacillus of Friedländer group, diphtheroid, *Bacillus influenzae*) is of one of the most recent bacterial "shotgun" mixtures, which takes the chance of one lucky bull's-eye in seven shots. No one can claim a scientific or even a common-sense basis for the treatment of a cold by such a mixture. It relieves the physician of the necessity of an etiologic diagnosis, discourages the search for contributing factors, and subjects the patient to uncontrolled experimentation with the "newest thing out." When one remembers that most of these so-called "mixed vaccines" are not vaccines in the sense of the word as used by Pasteur and Wright, that is, the bodies of killed bacteria in suspension, but are the "sterile aqueous solutions of metabolic substances generated by bacteria grown in artificial mediums,"[3] the possibilities of subjecting the patient to multiple intoxications, not essential to his recovery, are apparent. To inject a carefully prepared autogenous vaccine, that is, the centrifugalized and washed bodies of dead bacteria *similar to those* causing the disease, in the hope of stimulating immunity in a mild and gradual way, is a defensible procedure; but to inject the soluble products of half a dozen or more pathogenic bacteria is a species of privileged poisoning under the protection of professional usage which few physicians would attempt with the better-known inorganic alkaloidal poisons of the pharmacopeia.

So unscientific and discreditable is the present tendency that all reputable physicians, especially those who sincerely believe in a rational vaccine therapy, should insist, *first*, on an etiologic diagnosis, secondly, on an autogenous vaccine, and, *finally*, on the most careful and painstaking study by *both* laboratory and clinical methods of all phenomena before and after vaccination. The use of more than one vaccine in a given case need not be frowned on; if a lesion contains more than one organism, a corresponding vaccine for the secondary invader may be prepared; but the principle of the autogenous vaccine should be maintained. Commercial mixtures should be avoided at all times, especially if they contain the products of more than one organism. Only by following these rules in the study of large groups of cases can vaccine therapy be placed on a respectable basis. Perhaps cumulative clinical evidence thus obtained may yield eventually a scientific basis.

---

### VACCINES IN DISEASES OF NON-BACTERIAL OR DOUBTFUL ORIGIN

One firm which is extensively engaged in the exploitation of the mixed vaccine advertises that "practically all acute and many chronic diseases are caused by the metabolic products of bacteria,"[4] and proceeds to prepare vaccines for diseases the etiology of which is unknown, or at least doubtful. Like the Athenians, who in the fear that they might neglect an unknown deity, provided for the worship of the "unknown god," these manufacturers have their "mixed infection" preparation "applicable to the multiplicity of infections which may be said to be of questionable etiology."[4] This point of view which, it is a satisfaction to state, originated with the manufacturers and not with the profession, coupled with the assurance that vaccines can do no harm, has led to many absurdities in vaccine therapy, and as certain groups of physicians show more and more of a tendency to allow the commercial vaccine-makers to control their diagnosis as well as their treatment, it would seem advisable for the more carefully trained and less susceptible groups of the profession to act reservedly and to advise caution. A recent writer on this subject[5] has given, as example of some of the weird claims or suggestions made (for the most part this is true in trade, not medical journals) supporting vaccination, the use of mixtures of bacteria in the treatment of vertigo, pruritus ani, hay-fever, rheumatism, sciatica, gall-stones, appendicitis and heart-block. The extent to which the manufacturers have impressed the profession was demonstrated at a recent meeting of the most dignified, exclusive and presumably scientific of our national medical organizations, when one of its members discussed the relation of the streptococcus to heart-block and certain mental disturbances and the question of vaccine treatment of such conditions.

Rheumatism, diseases of the bones and joints, and allied conditions have come in for a large share of attention by the commercial maker of vaccines. The "Rheumatism Phylacogen," through a vast amount of advertising, is almost as well known as Ehrlich's salvarsan, but how different its origin and the method of testing its efficacy and of bringing it before the profession! The most ardent supporter of the view that certain forms of joint-trouble may be infectious or toxic in origin cannot accept the opinion of the manufacturer that the same treatment applies equally well to "acute rheumatic fever, acute articular rheumatism, acute inflammatory rheumatism, chronic rheumatism, rheumatic arthritis, rheumatic myalgia, rheumatic iritis, lumbago, sciatica."[4] Despite the inconsistencies of this classification of "rheumatic" (*sic*) affections, many physicians accept the advice, 'broaden the scope of their treatment and gladden the heart of the manufacturer by including many forms of chronic arthritis which he does not mention; but they are consistent to the extent that their additions include diseases of unknown or doubtful etiology. This they do in spite of the fact that the manufacturers definitely tell them that "failure of Rheumatism Phylacogen, properly administered, affords presumptive evidence of an error in diagnosis."[4] Not only is this Phylacogen, according to its supporters, a specific in treatment, but it is also a specific in diagnosis—the equal of quinin in malaria, of tuberculin in tuberculosis, a combined salvarsan and Wassermann reaction in one and the same package—and all this in a group of diseases of doubtful etiology!

To use conservative language, such treatment is purely empiric and wholly speculative. When the joint condition is associated with a focal infection in some distant part of the body and an organism can be isolated and an autogenous vaccine prepared, the use of the latter in addition to local treatment is a justifiable procedure, on the general theory of the vaccine treatment of local infections. When a local lesion cannot be determined and an etiologic diagnosis is therefore impossible, vaccine treatment, "mixed" or otherwise, is indefensible, both on the basis of rational therapeutics and of the ethics which control the physician's relation to his patient.

That many physicians claim excellent results for vaccines in the treatment of diseases of obscure origin is not conclusive. It is in just this class of diseases that the osteopath, the naturopath and others of the same group likewise claim most brilliant results for their peculiar methods. Who is to judge of the influence of a single factor in the treatment of disease? Has not past experience shown that early results with new cures are usually brilliant? How many diseases heal spontaneously or are improved despite any treatment? How important is the psychic influence of a new widely heralded treatment? And, on the other hand, are the unsuccessful results always reported; do we learn, except by accident, of the failure to improve and of sudden death due to the treatment? Many factors must be considered in arriving at an opinion.

The present attitude with regard to vaccination in diseases of doubtful origin promises little for either etiologic diagnosis or specific treatment, the two aims of modern medicine, nor does it aid that broader effort to advance social welfare, in the furtherance of which, medicine, if it is to remain a powerful factor, must be both safe and sane.

If the venturesome practitioner feels compelled to use vaccines in diseases of obscure origin, let him do so, supported by every aid which laboratory and clinical research may offer; but the wiser course, in the absence of a demonstrable local infection from which an autogenous vaccine may be made, is to leave vaccination to others. One fact, the essential mechanism of vaccination, must not be misinterpreted or minimized, and this is especially important in view of the advertised statement concerning commercial vaccines. The statement that "the growth of infecting micro-organisms can be arrested and their effects neutralized by the products derived from their development in artificial culture mediums"[4] is misleading in that it implies direct bactericidal and antitoxic action —which is not the case—and leaves out of the question the only rational explanation of vaccination, that it is the stimulation of the immunizing process in the host. This misleading statement of the commercial vaccine-maker is responsible for much of the misunderstanding concerning vaccine therapy and its curative value. As Theobald Smith phrases it, "Vaccines applied during disease will be rarely, if ever, life-saving, but they may hurry a stationary or languid process which tends to recovery, by hurrying into play the unused reserves of various tissues."

### SUMMARY

1. Prophylactic vaccination rests on a sound scientific basis of experimental study and clinical observation.

2. Curative vaccination has no sound experimental basis, but the application of the general principles of immunity as well as clinical observation offers a plausible basis for the treatment of localized, more or less chronic infections, and of "carriers." On the other hand, no satisfactory basis is at hand for curative vaccination in the acute self-limited diseases characterized by general dissemination and systemic infection. All attempted vaccinations in this group must be considered as purely experimental.

3. The only logical method of vaccination is the use of "autogenous" vaccine. Mixed vaccines, commercially prepared, constitute a type of bacterial polypharmacy which should be discouraged as unscientific and nonethical.

4. Therapeutic vaccination, if it is to be placed on a scientific basis, should be regarded as a method of treatment based on the study of the individual and his infection and not as a ready-made method capable of the universal application of stock vaccines. The use of vaccines in diseases of doubtful or unknown etiology is unscientific and ethically indefensible.

5. Every physician practicing vaccination should bring to bear in the study of his results every method of laboratory and clinical investigation which promises light, and preferably should work with a trained immunologist. Thus only can definite knowledge of the efficacy of vaccination be obtained. It is well to remember the words of A. E. Wright in this connection. Wright asserts that for such skilled service as that demanded by vaccine therapy "is required a man who has spent years of study to master the technic; to know how to make the vaccines, to know where to look for the microbes, to know which are the most important microbes, to know how to isolate them, and, most of all, a man with sufficient experience and ability to apply all these things."

6. In the interpretation of results it should be borne in mind that, as Theobald Smith has emphasized, vaccines rarely, if ever, cure, but act rather in aiding a process which tends to recovery by stimulating a languid process of immunization.

In the preparation of this paper I acknowledge the free use of two papers on the same general subject by Theobald Smith,[6] and one by F. P. Gay.[7]

# THE PROBLEM OF THE CRIMINAL IN THE LIGHT OF SOME MODERN CONCEPTIONS

HAROLD W. WRIGHT, M.D.
Assistant Alienist, Bellevue Hospital
NEW YORK

Since Lombroso enunciated his views as to the physiognomy of criminals which caused him to place them in a class by themselves, he has gained many adherents with views modified and extended. There has developed, naturally enough, an opposing army of thinkers who may be divided into those who place the blame for criminal offenses entirely on the social environment of the offender, including his training or lack of it from birth to maturity, and those who regard him as wilfully vicious even though morally defective, and therefore responsible for his actions.

It would seem that in the course of the controversy the latter view has steadily been losing ground, while the former has not as yet made good and has lost many from its camp because of disappointing results following half-hearted or impulsive attempts at prison reform without a clear understanding of the material dealt with.

More and more champions of the Lombrosian idea in its essence, namely, that the criminal is inherently abnormal, have come to the front with evidence more or less worthy, and criminology at the present time is fast becoming a medical science rather than a legal one.

Even before Lombroso's publication there appeared in 1870 an article by Bruce Thompson, resident surgeon in the prison at Perth, Scotland, which argued from the medical point of view in strong terms. To quote:

> On the borderland of lunacy lie the criminal populations It is a debatable region; and no more mixed problem comes before the medical psychologist than this, viz., where badness ends and madness begins. The inmates of asylums and of prisons are so nearly allied that thin partitions do their walls divide.

To quote again:

> From large experience among criminals I have come to the conclusion that the principal business of prison surgeons must always be with mental diseases; that the number of physical diseases is less than psychical, and that the treatment of crime is a branch of psychology.

He then lays down the following propositions:

> 1. There is a criminal class distinct from other civilized men.
>
> 2. The criminal class is marked by peculiar mental and physical characteristics.
>
> 3. The hereditary nature of crime is shown by the family history of criminals.
>
> 4. The transmission of other nervous disorders with crime in this class proves the alliance of hereditary crime with other diseases of the mind, such as epilepsy, dipsomania, insanity, etc.
>
> 5. The incurable nature of crime in the criminal class goes to prove its hereditary nature.

Whether these propositions are justified or not, they go to show the impression that a close study of the criminal made on a careful observer before the days of modern psychiatry and psychanalysis, before the realm of the subconscious mind had been explored by Charcot and Janet, Freud and Jung.

But this new school or phase of the subject is by no means on a footing sure enough to convince either the public at large or the legal profession of the justification for its point of view, nor has it received often enough that respectful hearing in the courts which would have prevented injustice being done not only to the prisoner at the bar, but also to society. Nevertheless, complete justice to both offender and society is slowly on the way, and even those who oppose or take no thought of the newer doctrines are unconsciously falling in line with them by their attempts to ameliorate the condition of the convict, by agitating for prison reform, indeterminate sentences, the parole system, and the changing of the prison into an institution for correction and custody rather than punishment. True enough, more of sentiment than of science is back of these methods, and therefore in many individual instances harmful injustice to society and ultimate harm to the offender against society is wrought. This is inevitable in any period of transition from an erroneous to a more correct method of dealing with social problems. As more harmony of opinion comes to exist among those who have been forced to take up the problem because of a contact gradually growing more intimate, justice to all will come nearer. And it is the psychiatrist, with his collaborator, the psychologist, on whom the responsibility must rest most heavily if the newer ideas of the nature of crime as a disease, of the criminal as a sick man, are to prevail.

There is no longer any credited opposition to the view that criminal offenses, petty or otherwise, are the products of individual and social disease. With the latter aspect of the subject I am not at present concerned. While the influence of environment, for those most charitably inclined, excuses the offender from responsibility for his condition, it does not excuse him from responsibility for his acts. But if every offender is a diseased person, in the psycho-physiologic sense, his responsibility must come into question before the bar of justice.

### QUESTION OF RESPONSIBILITY

Many a medicolegal battle has been fought over this question. The issue has been confused usually because the legal mind has ever thought of consciousness as synonymous with sanity. Because a man knew what he was doing the lawyer has held him responsible. But a man's mental make-up is a very complex thing; it is a bundle of psychic forces and habits which may be summed up in three divisions: intellect (or consciousness); emotion, that is, impulse to act; and will, that is, action itself. No two persons are alike in the strength or weakness of one or the other of these forces. To take the view that consciousness of the wrongfulness or illegality of an act at the time of its committal makes the offender "responsible" for it and legally sane, is inconsistent with the well-founded knowledge of mental functions which we now possess. Conduct is not dependent chiefly on knowledge, but much more on impulse or emotion and a will capable or incapable of controlling and directing impulse in a way to harmonize with knowledge, that is, consciousness.

It is just because of this complexity of function that so many different kinds of crimes are committed and so many different types of criminals exist, and the more or less inadequate classification of criminals that has been attempted by various writers will show when analyzed that consciously or unconsciously the classifiers have characterized the objects of their study according to the mental function most involved in them.

For example, Ferri, a follower of Lombroso, classifies criminals as follows:

1. The criminal by instinct, who is the born criminal.
2. The passional criminal, who commits crime under the influence of passion.
3. The criminal from chance.
4. The criminal from habit.
5. The insane criminal.

In the first group would be placed those who by reason of some inherent defect involving the intellectual and emotional functions are incapable of developing the sense of love, self-sacrifice, pity, honor, altruism or remorse—persons whose standard of right and wrong can never be the same as that of the average member of society in the period in which he lives. These are cases of arrested development in the ethical sphere and represent reversions in this faculty to primitive types.

Illustrations of the brute instinct which we all possess are seen in the class of criminals whose acts are due to passion, becoming, on sufficient provocation, beyond control because of weakness of will in the nature of a deficiency of inhibition power in the nervous system. Now it is known from physiologic investigations that the power of inhibition is a function of certain nerve cells and fibers in the cortex of the cerebrum.

In the case of the criminal from chance we are confronted with a feeble-minded person who is easily made the subject of suggestion because of deficiency of judgment and who responds to the criminal suggestion because of deficiency of inhibition. Persons of this kind are the tools of the more intelligent in crime, are harmless in themselves, and in an environment in which they are safeguarded from temptation they lead normal lives. They are children all of their lives in so far as their faculty of judgment and power of will are concerned.

In the class of habitual criminals are to be found those who by reason of environment, especially early environment, lead criminal careers in response to the association of ideas which their environment has aroused or which has been aroused by psychic shocks during the age prior to that of mature judgment; these shocks have affected the subconscious mind in a way to make it seek relief in periodical reaction, usually of a resentful, retaliative nature. Such a career is for them the path of least resistance. The first crime has relieved the depth of the subconscious mind from tension, and thus aroused in it sufficient pleasure or desire to cause disassociation of emotion from intellect at the time when the opportunity to commit the crime again occurs. Persons of this kind form the class of recidivists or repeaters, and it is noteworthy that prison officials have reported that the subsequent offense of the recidivists is exactly like or similar to the preceding one. Their condition may be compared in a measure to that of the kleptomaniac, in whom, however, there is a much wider disassociation of consciousness and who is more definitely insane. They may also be compared or likened very closely to the hysterical patient as regards the essence of the disorder. Janet shows clearly the nature of the weakness of will and of obsessive ideas and their consequences in this type of mind, for example:

> This feebleness of will and of attention is, in fact, manifested by a second characteristic which seems the inverse of the preceding (suggestibility), and which, nevertheless, is its logical consequence. Just as hystericals are incapable of beginning an action, starting a belief, or a perception, so are they equally incapable of stopping any when once started. To stop an action is to change our general state. It is to adapt ourselves in another manner to a new circumstance. These patients, who understand no change, understand still less such an one, for it is necessary to create a clear and powerful thought in order to stop the automatic development of an old

thought that has become stronger and stronger through repetition. "When I have begun something," we heard a patient say, "I must go on with it; I cannot stop; I would break the windows, kill myself—I am pushed on by my ideas; driven in a way that I cannot resist—I fall into an idea as down a precipice, and the declivity makes it hard to get back again!"[1]

In the definitely insane group of criminals, that is, those having one of the clear-cut psychoses, there are all grades of mental disintegration involving, as in the borderland cases, one or more or all of the functions of mentality. Those most prone to commit statute offenses are the paranoiac, with his disruption of judgment; the epileptic, in whom consciousness is almost entirely split off and who at the time of the act is almost entirely a subconscious automatic personality; the kleptomaniac; the dipsomaniac; other drug habitués, especially the cocain fiend, who may commit violence in reaction to hallucinations. Responsibility for crime committed by persons of this kind can be at once dismissed.

But when there are offenders of the first four classes enumerated to consider, we are brought face to face with the "borderland cases" in psychiatry. These comprise that vast number of unfortunates who are psychopathic, but are rarely committed to hospitals for the insane and are so disposed of only in their episodal periods of excitement or quarrelsomeness. When they recover to their usual level they are again discharged into society no more fit than before to cope with its complexities. Among these are the ones who commit petty offenses for which they are sent to jail, workhouse or reformatories for short terms; after their release they soon are returned because of inability to get along in any environment in which they are not closely subjected to organized discipline. They behave very well in custody, and if kept so for prolonged periods would gradually develop habits of self-control, concentration of mind and industry, which would make them self-supporting in occupations fitted for their capacities. The vagrant, the brawler, the gangster, the prostitute, cadet and the ne'er-do-well all belong to this group. They have been called by several writers "constitutional inferiors,"[2, 3] and this is a correct term to apply to them, if the particular function of mentality in which they are inferior is designated.[4, 5] Otherwise the term is unsatisfactory, for in some of their capacities many of them are found to be exceptionally brilliant, or at least superior to the average, that is, in music, drawing, literature, invention. For these, one writer prefers the term "constitutional abnormality."[6] The sort of offenders just described may be found in any of the first four groups of Ferri's classification, as may those who commit more serious offenses, crimes which are punished by long sentence in the penitentiary or state prison.

All offenders, indeed, may be characterized by one or more of the following attributes:

1. Exaggerated suggestibility.
2. Exaggerated egotism.
3. Emotional instability.
4. A lack of altruistic or unselfish sense.
5. A lack of the power of sustained energy, that is, abnormal nervous fatigue.
6. A tendency to the easy disintegration of consciousness which permits the brutal or inferior qualities of the subconscious mind easily to become dominant when temptation occurs and to be ungoverned by the critical quality of the conscious mind; even when the critical function is sufficiently aroused, the power of direction by the will is in abeyance. Here is again seen the similarity in mental make-up of these persons to that of one afflicted with hysteria.

### THE QUESTION OF SANITY

It is not my purpose to attempt to account for these abnormalities of conduct by theoretical consideration of the pathologic nature of them in so far as brain structure is concerned. Too little is known, too little can be known, of what constitutes complex brain function. But it can be confidently asserted that in every person of the types above considered we are dealing with a mentally abnormal person — therefore not a sane person, but a *diseased person, a sick person*, as well as an *offender* against the laws of the society in which that person lives —laws to which perfectly sane or well persons have no difficulty in conforming.

### TREATMENT OF THE CRIMINAL

If the views just expressed are true to the best of our present knowledge, any method of dealing with the offender which contains an element of punishment is unjust to him and also illogical. It is likewise unjust and illogical from the point of view of the protection of society; for the idea of punishment necessitates fitting the punishment to the crime and not to the criminal. When the allotted punishment is completed, the criminal, unchanged, is set free. Society has the right to protection, the individual the right to justice; but the only real justice for the person who is in error is the attempt to correct the condition which caused him to err.

Does punishment do this? Have crimes decreased in the aggregate or in the individual case because of the customary penalties imposed for them? Statistics do not warrant any such assumption. In the United States from 1885 to 1906, murder and homicide increased from 32 per million inhabitants to 108 per million, while the number of executions in the same period increased from 17 to 76. The number of those in prison for all offenses decreased by 30 per each 100,000 inhabitants during this period. An increase is also shown in less serious offenses.[7] If these statistics mean anything, may they not go to show that the habitual or instinctive criminal is too often set free to repeat his errors and also to influence the unrecognized, potential criminal of the feeble-minded, constitutionally inferior class? It is the instinctive or habitual criminal who often is pardoned for good conduct, because of his ready adaptability to prison life when he knows such an attitude to be for his advantage. In these offenders, however, punishment only arouses a desire for retaliation on society.

What, then, is the remedy? Are we to abolish prisons and penalties and, taking the fatalistic view that all crime is incurable, shut up all offenders in asylums for the remainder of their lives?

Abolishment of punishment is certainly called for and is gradually coming as the prison is changed into a house for correction and custody, into a colony for abnormal people—where they may live as nearly normal a life as is possible for each and every one of them, where their individual characteristics and capacities are studied and their lives arranged accordingly. The same change has

already occurred in the methods of dealing with the obviously insane, as may be seen by a visit to the most up-to-date state hospitals. If these methods are worth while in the case of the chronically insane, they are still more so in the treatment of criminal offenders who, though mentally abnormal, are, in the majority of instances, amenable to much greater improvement in habits of thinking, feeling and acting.

But such treatment cannot be accomplished without the supervision and cooperation of the medicopsychologic profession. It is perfectly possible for those who have associated for a long time in a professional capacity with psychopathic persons to determine who is amenable to this, that, or the other form of correction, and to tell when the person is sufficiently corrected in his neuropsychic functions to justify his parole into normal society.

It is also perfectly possible for such trained men to determine who should be kept in permanent custody. It is not possible for those of the legal profession to determine these questions justly unless they also have had the training of the physician and the psychiatrist. Nor is it possible for them to frame just laws as to penalties.

It is not unreasonable, therefore, to foresee the time when the function of the lawyer and the judge will be restricted to the determination of the guilt of the offender and the function of prescribing what is now called the "sentence" or "penalty," but which some day will be called the "therapy" or "treatment," will be taken over by physicians thoroughly trained in mental diseases, who are in the service of the state and consequently free from bias in judgment.

Prison reform must come from within, in response to the conception of crime which scientific study of it as a medicopsychologic problem engenders. Prisons will then become therapeutic schools and colonies controlled by men who know well the sort of material they are dealing with.

These methods and this attitude of mind already prevail in many of our large cities in respect to juvenile offenders. In many juvenile courts a thorough physical and mental examination, including family and developmental history, is made before the judge takes up the case, the offender being detained in a detention home long enough to accomplish the examination. The disposal of the case is likewise influenced almost entirely by the opinion of the medical examiner. If these methods are proper and practicable in dealing with juvenile cases, why are they not also proper for those of a larger growth who are yet children in respect to their development of the moral sense, the will, intellect, self-control, etc.?

Leaving aside the question of the present method of dealing with the major crimes, such as murder, arson, homicide, grand larceny, will any one question the need of reform along the lines suggested in the treatment of minor offenses? Can anything be more ludicrous as well as pitiable than to send the drunk and disorderly, the vagrant, the prostitute and the feeble-minded who have fallen into bad company to the jail or workhouse for a few months, there to find associations and influences worse than they have ever before been in contact with, and then to turn them loose to vent their pent-up feelings in a way which is only a natural response to the lower instincts which such treatment has stimulated!

Let us hope that the day is not far distant when all criminal offenders, "petty" or otherwise, will be looked on in the spirit of compassion, in the light of scientific insight, and their offenses considered symptoms of psychic disease.

# THE ETIOLOGY AND VACCINE TREATMENT OF HODGKIN'S DISEASE

## PRELIMINARY NOTE *

FRANK BILLINGS, M.D.
AND
E. C. ROSENOW, M.D.
CHICAGO

This note is published at this time as a confirmation of the findings in Hodgkin's disease of Bunting and Yates,[1] and Negri and Mieremet,[2] and to call attention to the apparently marked benefit following injections of the heat-killed organisms found in the lymph-nodes.

A Gram-staining, non-acid-fast, polymorphous diphtheroid bacillus corresponding to the one found by Fränkel and Much[3] in smears, and cultivated successfully by Bunting and Yates and Negri and Mieremet has now been isolated from the lymph-nodes in twelve cases of Hodgkin's disease. It was obtained in pure culture in only three cases, while in the rest it appeared in conjunction with a staphylococcus. Whenever possible, a portion or all of two lymph-nodes were removed, one from the group involved the longest (usually the cervical region), and one from the group most recently involved (usually the inguinal region). In addition to planting small pieces of the lymph-node, emulsions in salt solution were prepared by grinding in a sterile motor in sterilized air, and planting the emulsion on blood-agar, blood-serum slants (aerobically and anaerobically) and into ascites-dextrose agar. The latter method has the advantage of yielding earlier and more uniformly positive results. By this method the minimum number of viable organisms and a relative proportion of those present has also been determined. In this way it has been found that the lymph-nodes involved the longest in a given case or those from cases of long standing showed more organisms and a relatively larger proportion of staphylococci, while the more recently involved lymph-nodes or those from the cases of shorter duration showed fewer organisms, but a relatively larger proportion of bacilli.

The marked pleomorphic character of this organism as pointed out by Bunting and Yates has also been noted by us. It has happened repeatedly that single colonies in the dextrose-agar, which showed bacilli only in smears, yielded in subcultures a pure culture of staphylococci aerobically, and forms of the bacillus either pure or in mixture anaerobically on the same medium. These facts suggest strongly that the associated staphylococcus is derived from the bacillus.

The vaccines are prepared by growing the organism isolated on the surface of Loeffler's blood-serum, ascites-dextrose-agar or blood-agar slants for from twenty-four to forty-eight hours. A suspension in salt solution is made, the clumps broken up as much as possible, and thrown down by fractional centrifugation. This clump-free emulsion is now standardized and heated to 60 C. (140 F.) for thirty minutes or one hour. Aerobic and anaerobic cultures are made on Loeffler's blood-serum, and these are incubated at least three days before the vaccines are used, to insure the sterility. Then phenol

(carbolic acid), 0.5 per cent., is added, and the treated killed suspensions are placed in the ice-chest for use. Whenever staphylococci were found, an attempt was made to have the vaccine contain the bacilli and cocci in about the proportion found in the lymph-nodes. It is obvious, therefore, that an autogenous vaccine is to be preferred, although good results have been obtained with a vaccine prepared from a series of strains isolated from different cases.

All of the patients presented lymphocytomas, all showed involvement of the cervical lymph-nodes, the majority had enlargement of the axillary lymph-nodes; the inguinal lymph-nodes were moderately enlarged in all of the patients; in four the mediastinal lymph-nodes were so large as to cause respiratory and cardiac embarrassment, with anasarca in two and pleural effusion in two patients. The spleen was palpably enlarged in ten and very large in five of these.

Histologic examination was made of the lymph-nodes of all the patients. The majority may be classed as the endothelioid type (Reed, Longcope, McCallum and others). One was classed histologically as lymphosarcoma and the remainder as simple lymphoma or lymphadenoma. The one patient with the histologic diagnosis of lymphosarcoma did not present clinical evidence of malignancy by general debility, anemia or recognizable metastases. As stated, the diphtheroid bacillus of Bunting and Yates was isolated from the lymph-nodes of all these patients irrespective of the varying histology of the lymph-nodes.

The blood-picture varied with the physical condition, length of illness and the absence or presence of fever. When present, the anemia was of the secondary type. Moderate leukopenia with relative increase of the small mononuclear cells was noted in some of the afebrile patients. Leukocytosis with the usual leukocytic formula occurred in most of the febrile patients. Four patients were febrile at periods. The temperature curve was of the remittent type. Seven patients were treated for long or short periods at the Presbyterian Hospital, Chicago, and were kept at rest. Five were under the care of physicians at home. Roentgenotherapy three times per week was applied to six patients at the hospital and was used with three of the patients under the management of others. Autogenous vaccine was used in all but one patient, who received the vaccine prepared from other patients. The vaccine was first given in the dose of from 5 to 10 millions and gradually increased to a maximum of 100 millions. The vaccine was given subcutaneously and repeated every five to seven days. We have not used it intravenously, but have considered that method of application in obstinate and extreme conditions. In febrile patients the second or third dose has been associated with a reaction consisting of an increase of temperature (in one patient to 107 F.), rapid pulse and general weakness and discomfort. In non-febrile patients only slight general reaction may occur with a rise of 1 or 2 degrees of temperature, slight general muscular aching and debility. But slight local reaction at point of injection occurs.

In six of our hospital patients there was a uniform and relatively rapid decrease in the size of the lymph-nodes—one of these without Roentgen treatment. One patient treated out of the hospital without roentgenotherapy, with very large lymph-nodes, big spleen and febrile, had a violent general reaction with the third vaccination, then became afebrile and the swellings of the lymph-nodes and splenomegaly rapidly diminished. After five vaccinations, this patient passed from our control and observation. Reports from physicians on two of the series show favorable progress with gradual diminution of the tumors of the lymph-nodes and improvement in a general way. One of these patients receives Roentgen treatment also; the other vaccines only. Two of the patients are dead. One with rather rapid enlargement of the mediastinal lymph-nodes died soon after the third vaccination, from the result of mediastinal pressure. This patient was managed at his own home by the family physician and the final clinical details are unknown to us. One patient with enlarged mediastinal lymph-nodes suffered for a year with respiratory and cardiac embarrassment. Right pleural effusion required frequent tapping. Under other care he received roentgenotherapy. A short period before death we isolated the micro-organism from lymph-nodes of the neck and groin and from lymphoid tissue removed from the nasopharynx. The patient died from the result of mediastinal pressure after only one autogenous vaccination.

Of patients under our continued observation one is apparently well. There are no palpably enlarged lymph-nodes; the much enlarged spleen is no longer palpable; the blood-picture is normal; his weight and strength are normal. One patient who suffered from much enlarged mediastinal lymph-nodes and consequent dyspnea, anasarca and great debility was very much improved with diminution of the size of all involved lymph-nodes, gained in weight and was subjectively comfortable, and has had the vaccines and Roentgen treatment every week since June. In October a remittent type of fever developed with gradually increasing anemia of the secondary type, a leukocytosis of about 18,000, with 80 per cent. of polynuclear cells. There was no increase in size of lymph-nodes. On November 24 she returned to the hospital. With rest in bed with vaccines, roentgenotherapy and good food there is again rapid general improvement. The other patients are improving with varying degrees of rapidity.

This preliminary note is presented with the hope that the clinical study may be carried on by others. We hope to present a more detailed report of these and other patients with protocols, definite histology of the lymph-nodes, blood-pictures, immunologic studies of the blood, etc. Finally, we have used Roentgen treatment coincidently with the vaccines, because we believe we were not justified in depriving the patients of any and all sources of help, even if by so doing we deviated from the narrow and definite path of scientific research. If it be finally proved that this micro-organism isolated from the lymph-nodes is the cause of the clinical entity called Hodgkin's disease, the use of the specific vaccines without roentgenotherapy may then be justified.

**Hydrochloric Acid and the Administration of Acids or Alkalies.**—T. Gillman Moorhead (*Dublin Jour. Med. Sc.*, Oct. 1, 1913) says that the presence of HCl in diminished or increased quantity is no definite guide to the administration of acids or alkalies, respectively, and that in treatment the stomach cannot always be expected to respond in a manner similar to the reactions in the test-tube. In some cases treatment along definite chemical lines is useful, as in hypochlorhydria, in which tonics and acids are beneficial, but in these cases also alkalies administered some time after a meal are more symptomatically useful by neutralizing the organic acids present on account of abnormal fermentation. In hyperacidity due to HCl, the removal of the cause, such as excessive smoking, excessive drinking, or excessive nerve strain, is much more useful than alkaline treatment.

# ETIOLOGY OF ARTIFICIAL FEEDING

## A PLEA FOR THE STUDY OF BREAST-MILK PROBLEMS *

HARRY LOWENBURG, A.M., M.D.
Assistant Professor of Infantile Dietetics, Medico-Chirurgical College; Pediatrist to the Mount Sinai Hospital; Assistant Pediatrist to the Medico-Chirurgical Hospital and to the Philadelphia General Hospital
PHILADELPHIA

The title of my paper expresses the desire that prompts its presentation—a wish to discuss, from actual clinical experience and from general observation, the reasons that lead up to a discontinuance of breast-feeding and which, therefore, bring about the institution of artificial feeding, and to prove that these reasons are usually fallacious. I shall not deal in statistics or cite classified groups of cases, but simply present the impressions which I have gained while following a clinical experience culled from private practice and from a comparatively large hospital clientele. The type of patients considered embraces a mixture of all classes, from the poverty-stricken alien who has but recently come to our shores to the infant of the rich surrounded with every luxury that the best city or suburban home can afford. The question is asked of every mother who presents an artificially reared babe or one on whom artificial rearing is being attempted, "Why did you take your baby from the breast?" In each instance—it matters not what the social status may be—the answer may be classified under one of three roughly made headings: (1) psychic, (2) educational, (3) economic or social. The divisions are not always distinctly separated, as a given reason may be embraced by one or more headings.

### PSYCHIC REASONS FOR DISCONTINUING BREAST-FEEDING

The psychic reasons may as a rule be referred to the maternal mental state at the time. How is this produced? The breast-feeding is usually discontinued through an innate fear either of not being able successfully to accomplish the act of nursing through not knowing how to go about it or through a fear that the product of the mammary gland is sufficient neither in quantity nor in quality to supply the nutritional demands of the infant. Either state is induced by a failure of the mother to recognize the possibilities of her own organism or through an instinct of unfounded anxiety for the welfare of her offspring. The reverse—a rare manifestation of innate selfishness—may be operative. In either of the two former instances the psychosis, if it may be so called, usually has no foundation in fact, or the temporary cessation of the lacteal flow is directly inhibited by the fear on which it depends. This inhibition of secretion finds its analogue in an identical effect on other secretions, notably that of the saliva, when the same etiologic factor, fear, is in evidence. Unfortunately, as will be pointed out later, the profession, by a tacit acquiescence in the probability of the actual disability or, in many instances, by actual encouragement in the idea, is often to blame, if not for the beginning of the trouble, at least for its continuance.

Here the physician loses a golden opportunity of becoming a legitimate psychotherapeutist and, by the same exhibition of indifference or of actual carelessness in other psychasthenic states, permits the irresponsible exponents of questionable systems of mental therapy to succeed where he fails. It is my experience that this element of fear of not being able to accomplish the nursing function successfully is one of the most important factors in the discontinuance of breast-feeding, and I wish here to subscribe to the opinion that rarely, if ever, other things being equal, in an otherwise healthy woman, can a permanent organic, irremovable obstacle to successful maternal nursing be demonstrated.

"I did not nurse my baby because I could not." "My milk poisoned my last baby and it died." Parenthetically, it may be stated that it was not the mother's milk that poisoned the baby, but in all probability the indifferent artificial feeding on which it was placed when the breast was unnecessarily withdrawn. "I never can nurse my babies because my milk dries up." These and similar replies are given to our queries as to why the breast-feeding was discontinued, and not one of them will stand the test of careful scrutiny or of future experience in a birth that is intelligently managed. Repeatedly in physicians' families have I seen instances in which I have been summoned, two or three months after unsuccessful artificial nourishment had been attempted to rear an infant because this element of fear had caused the breast-feeding to be discontinued; while in subsequent deliveries in which the care of the breasts had been placed in my hands and the mother had been properly fed and encouraged and morally supported and all external interfering sources had been excluded, a period of successful nursing has ensued which lasted nine or twelve months and could have continued longer had I so wished. Who among you has not had a similar experience?

The fear that the breast-milk is not the proper food for the infant often depends on the development of the signs of early indigestion—vomiting and green-curded stools, and a failure to gain immediately in weight. This will be referred to again, as it involves the physician's responsibility. Suffice it to say that green stools and vomiting do not constitute a bar to successful nursing, although I have found them to be among the most common causes that put to flight the physician in his half-hearted attempts to conserve the breast to the infant.

Among the better element a pretense of willingness to nurse is often made while at the same time every possible excuse is seized on by the mother in an effort to demonstrate her inability. The exigencies of social life, an inordinate love of pleasure, the confession of utter ignorance and helplessness, a desire to escape the obligations of maternity and to shift them on others, a cowardly exhibition of hysteria or assumed physical weakness underlie the plea for assistance. I know no class of patients more difficult to handle; I know no more disheartening task than to convince such mothers of their error. They must be handled diplomatically, yet withal sternly, the conscientious physician refusing to be ruled by them or to acknowledge the incorrectness of his position. One must appeal to their moral sense, the duty which they owe to their offspring, and point out to them the uncertainties and dangers of artificial feeding. The climax usually comes by the mother seeking advice from one of a more conciliatory mold. Few will yield when once they have determined to seek the services of the bottle until perhaps it is too late—in the presence of a fatal diarrhea, convulsions or pneumonia.

### EDUCATIONAL REASONS

The reasons given that may be classified as coming under educational deficiency call into account both the physician's and the mother's responsibility. Infant-feeding, in spite of the so-called advances made in the science, is neither properly taught in medical schools,

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

nor is it properly presented in most of the text-books, or practiced, as taught, by the leading dietitians in their hospitals or in private practice. I do not imply that the text-books fail to present the subject of artificial feeding thoroughly. On the contrary, the authors' attempts at comprehensiveness befog the issue. Too many views, too many theories and too many methods are still being taught. Students and practitioners when through perusing this or that authoritative work, or all of them, are left without the ability to apply practically what they have read. I was amazed recently when visiting the wards of one of the largest institutions of a certain city to find that the feeding cases were left by a distinguished chief in the hands of an inexperienced intern, who in his turn depended on a nurse of less experience. Stock mixtures, carelessly compounded, were fed. All the babies were doing badly. Answers to pertinent questions were evasive. Knowledge of metabolism, digestion and of the adaptability of the mixtures to the individuals was lacking. The wonder is, not that the average physician still refuses to be impressed with the value of scientific feeding, but that he ever attempts to follow out any case to its logical conclusion.

If this be true of artificial feeding, what may be said of the teaching and practice of breast-feeding? It is almost nil. The student and practitioner receive but little information as to how to interpret or to meet the signs of early indigestion, as to what are the best means of conserving the milk-supply and how to meet the problems of nutrition as they occur in the breast-fed. Authoritative opinion satisfies itself by stating that the best way to rear an infant is on the breast and, after demonstrating that the great yearly infant mortality depends largely on conditions attributable to artificial feeding, proceeds, without further comment on breast-feeding, to elaborate page after page of instruction on that means of feeding on which the greatest mortality depends. The paradox is real, since the conservation of human milk may be successfully practiced.

A breast-fed infant has colic: it is constipated or has diarrhea; it vomits; its stools are green and contain mucus and curds. None of these constitutes a bar to successful breast-feeding. With reference to vomiting itself I wish to state that, though it need rarely be so, it is one of the most common causes for withdrawing the breast. In all I have treated eight cases of pyloric obstruction, and in each instance maternal nursing had been discontinued because of the symptom—vomiting—the diagnosis of obstruction not having been considered. A little care and use of the ordinary methods of physical diagnosis would have determined that the cause of the vomiting depended not on the mother's milk, but on an organic stomach affection.

On the other hand, vomiting dependent on faulty milk, as an excess of fat, or on overfeeding or too frequent feedings, does not constitute a valid contra-indication to the use of the breast. Dietetic, eliminative and mechanical treatment of the mother and the institution of common-sense hygienic measures will speedily correct the error.

An infant cries a great deal; it does not seem to get enough milk; it is said to be hungry after nursing; it does not gain in weight rapidly enough; the milk is too thin or too rich, scanty, or entirely absent. Only once in a healthy woman, in a case seen with Dr. Victor A. Loeb, have I met a real instance of an entire absence of milk.

"The mother is too nervous or too irritable." "She is too weak." "All her strength goes into the milk." These and many similar statements are made by the mother, or her friends, or the physician, or all, as an excuse to abandon the breast entirely or to institute partial artificial feeding. Just as vomiting and indigestion rarely constitute a valid reason, so too it may be demonstrated, though time and space forbid detailed consideration of each supposed contra-indication, that none of the many reasons stated are really legitimate bars to maternal feeding.

Abscess of the breast need not, in my experience, in every case indicate complete withdrawal of the breast. The size, location, duration and whether or not pus is secreted at the nipple are the determining factors. If, then, it can be proved that the statement with reference to these supposed contra-indications be true, where does the responsibility lie? What may be done to offset the pernicious tendency to credit these really trivial reasons with such great etiologic influence? Physicians must be educated first to recognize the possibilities of the breast, and they in turn must educate the mothers. The specialist must set the example for the practitioner. Instead of espousing this one's or that one's method of artificial feeding, let him see to it that he is known as an actual and practical advocate of breast-feeding. Let him refuse to place an infant on the bottle just because it is brought to him for this purpose, unless he is presented with a sound reason and one not founded on fear or fancy. Let him, by actual weighing experiments before and after each feeding, satisfy himself as to whether or not the infant is receiving sufficient food. He should consider the weight of the infant at birth, its present weight and its average gain before he determines the nourishment to be unfit. If it be found so, let him make an honest endeavor to rehabilitate the lacteal flow before confessing failure. The need for systematic propaganda is urgent, and to be given authoritative weight it should emanate from the Section on the Diseases of Children of the American Medical Association. We should cease arguing about percentages and calories, the etiologic importance of protein, fat and sugar, the rôle that bacteria play, nitrogen intake and ammonium output, the effect of calcium and potassium salts, the two-hour interval, or the four-hour interval, spasmophilia and the exudative diathesis. Let us cease teaching something to-day and decrying it to-morrow, but let us unitedly declare to the profession and to the motherhood of America that the only correct way to feed infants is on the breast, and then let us teach them how to do it.

The artificial feeding of infants has engaged some of the brightest minds of the profession. From the first attempts of Meigs and Pepper in America to adapt cow's milk to the digestive apparatus of the human infant down to the present day illustrious students, Jacobi, Rotch, Holt, Chapin, Finkelstein, Meyer, Keller, Czerny, Heubner, Rubner and others, besides a host of diligent laboratory workers, the trend of investigation has been along lines leading toward the solution of this problem. In spite of years of effort it has been but partially solved. Some uniform rules of feeding may have been enunciated, but no one food, or one method or one system of feeding has been determined as universally adaptable to the human infant. Have the years spent in patient toil and profound study been for naught? This query may be answered negatively if the profession realizes that it has not solved artificial feeding, and positively if it is not conscious of its failure and at the same time that it has not utilized the advantages of breast-milk feeding. Could one-tenth of the time and study devoted to the investigation of artificial feeding have been diverted toward the consideration of the conservation of human milk and of the causes which lead to its disuse and of the means of treating and meeting the gastro-intestinal and nutritional disorders of the breast-fed, infant mortality would have speedily and materially dwindled. The efficiency of breast-milk as a prophylactic against acute infectious diseases, rickets and scurvy, and its therapeutic value in many instances in combating a fatal issue, is well recognized but too seldom utilized. In private practice the incidence of an acute infectious disease is almost invariably the signal to discontinue breast-feeding. The mother is actuated by fear. The physician displays a lack of knowledge in conducting the feedings during the interim. Here is a case in point:

Case 1.—An infant of 3 months with an acute empyema was admitted to the Philadelphia General Hospital. Bulging and redness appeared between the ribs. The empyema ruptured and the opening was enlarged and drainage instituted. After recovery, measles and, later, pneumonia of the opposite side developed, and still later the infant had convulsions. The treatment consisted alone of continuous breast-feeding and ordinary hygienic measures. No drug therapy was employed, and recovery was complete. To-day the baby is a fat, rosy specimen, with but the scar of the empyema remaining.

It would not have taken a great stretch of the imagination to prognosticate the fate of a poorly nourished, anemic, rachitic, indifferently artificially fed infant of this tender age under like circumstances. Breast-milk saved this baby's life and it will do likewise for others. We know well the effect of wet-nursing in many cases of decomposition( marasmus), which cannot be made to gain. The point is not that we do not possess the necessary knowledge—not that the case cited presents anything new—but that we fail, in our zeal to delve deeper into new methods of artificial feeding, to realize the treasure we possess in breast-milk, or, granted we do, we fail to put our knowledge to use. We are as

> one whose hand,
> Like the base Indian, threw a pearl away,
> Richer than all his tribe.

The indifference with which physicians sacrifice the human breast is nothing short of shocking, especially since they possess nothing quite so good to offer. Even to-day the woful lack of knowledge possessed by many practitioners as to how to adjust cow's milk to the needs of the individual is appalling. The cynical manner in which they regard the whole subject of scientific artificial feeding is disheartening. They are the chief offenders. They usually have many poor persons who seek their advice. It is among this class that the ravages of mortality are the greatest. It is these physicians we should reach. They are in need of propaganda which will educate them in the methods of breast-milk conservation.

According to my observations, maternal illness need not constitute a valid permanent contra-indication to breast-feeding in the majority of cases in which it is practiced. This has special reference to slight indispositions, colds, mild infections and minor operations. The ease with which the breast-milk may be rehabilitated can be witnessed daily, after a cessation of many days and even weeks. A wet-nurse was discharged from a case. The infant exhibited an idiosyncrasy to cow's milk. Persistent efforts were made for three weeks with the bottle. Rashes and gastro-intestinal symptoms developed (allergy). The wet-nurse was recalled. Her milk was found to be scanty and poor. Under forced feeding, general hygiene and the stimulus given to the mammary gland by the infant's lips, the fluid was reestablished to overflowing and reached a percentage of fat above 7 per cent., and measures had to be taken to reduce both quantity and quality. Eclampsia, nephritis, grave anemia, malignant disease, tuberculosis, certain forms of cardiac disease, pregnancy, epilepsy, insanity and prolonged infections are the type of illnesses which contra-indicate nursing.

The obstetrician, too, must assume his share of the responsibility in this war of conservation. He must be a breast-feeder enthusiast and should be capable, without the advice of the pediatrist, of handling the problem for at least the two or three weeks of his attendance. Beside his indifference to features other than those directly connected with the accouchement (care of the breasts, inquiry as to the condition of the nipples and the character of the milk, etc.), the greatest error into which he falls is to allow his patient to get out of bed too soon. This is usually followed by bleeding, which is deleterious to the quantity and quality of the milk. One obstetrician of my acquaintance is accustomed to give his patients a dose of Epsom salt daily after the third day. The result is that nearly all of his patients have bottle babies. This case illustrates what may be accomplished:

Case 2.—One of his patients, the wife of a physician, had received a dose of Epsom salt daily for two weeks. Her milk was practically gone. She was anemic and undernourished, as was the infant at the age of 7 weeks. It was on the bottle in midsummer. The parents were much alarmed, as their first baby had died of intoxication (Finkelstein). Forced feeding, sensible hygiene and a tremendous amount of moral support rehabilitated the milk-flow and carried the infant through the summer and far into the winter with exceptionally satisfactory results.

### ECONOMIC REASONS AGAINST BREAST-FEEDING

Reasons for stopping breast-feeding, at once pathetic and difficult to overcome, are those which may be classified as economic or sociologic. No one denies that the poor and ignorant are in need of instruction in hygiene and general physical care. It may be pertinently asked, however, whether or not such instruction brings about desired results. Those who come into daily contact with disease the result of poverty, and endeavor to inject personality into their work and aspire to be more than medical men and to make their hospitals and institutions educational forces, often realize how hopelessly useless is the task. We are reminded of a saying accredited to Henry Ward Beecher that the most potent factor in the reformation of a hungry man is a sandwich. So these mothers, who are poorly housed and poorly fed, who must labor either within the home or outside of it, are best benefited by that advice which comes as actual material assistance to relieve, in part at least, their physical responsibilities.

On whom does the onus rest? On society itself and its representatives—the legislature. Free milk-stations, floating hospitals, clean milk and many other endeavors, providing what appear as luxuries to the poor, but which, as ordinary necessities, are secured, as if by divine right, or at least without the influence of visible external agencies, by those better situated, represent a well-intentioned but misdirected expenditure of thousands annually by the state and charitable organizations. Under our present social system, however, the necessity seems to exist. What else, other than charity, have we to offer to the mother who answers our demand that she nurse her babe by affirming that she must go to work; that she has not enough food to provide the ordinary fare, without considering the extra quart of milk which she must consume; that she must place her babe in a home or in a day nursery. Recently in Pennsylvania an act has been passed pensioning indigent mothers instead of separating them from their children by placing the latter in public institutions. While accomplishing some good its effect cannot be far-reaching, since it is practically a form of charity, itself a result of perverted social conditions and by its nature necessarily limited in its scope.

Further, it may be pertinently queried whether or not the permanent necessity for charity exists, and who is to determine who shall receive charity and who is to dispense it. In other words, why do poverty and its companion, ignorance, exist? Is it not possible that the error lies at the foundation of our social system, which denies to the worker his rightful share of that which his brawn has built, and gives the lion's share to the brain which conceives or directs? As a consequence his opportunities for education and self-uplift are limited. Does not charity simply represent a return by the individual or by the state of that which originally should have been given to the beneficiary as a product of his labor? If this be so, does it not appear patent that the necessity for charity not only does not exist, but that it is not humane and that, as before stated, it is makeshift and a blight on the state which encourages it?

One may ask, in what manner does this influence infant mortality in general and the problem of breast-feeding in particular? Its effect is potent largely for the reasons enumerated and because it hinders the independence of the nursing mother. It is recognized that however desirable an economic revolution which would benefit this class may be, its fruition and practical realization are not only problematic, but also far remote. The innate selfishness of human nature, the self-love, the exaggerated ego from which we all suffer, will indefinitely postpone the millennium of equal opportunity to partake of the natural resources of the earth and of the common well of knowledge. One fact stands out clearly, and that is that the nursing mother is performing for the state a duty not only as real but far more important than the artisan who is legally employed to build its bridges or to construct its highways. Why deny compensation to the one and not to the other? Let that mother who is devoting from nine months to one year of her time to the rearing of a future citizen of the commonwealth be relieved of material responsibility and be paid in actual cash for her services. This need not be regarded as chimerical but could, I believe, be put into practical operation and would redound to the good of the nation and would be a far more sensible expenditure of the public funds and certainly more humane than doled-out charity. Before legislators could be prevailed on to lend their influence to such a proposition the motherhood of the country and the profession are in urgent need of illuminating propaganda which would emphasize the advantages and possibilities of breast-nursing, the dangers and often the lack of the necessity for artificial feeding and the tremendous influence of the latter in maintaining the high-water mark of infant mortality. The burden of such a campaign of education is on that portion of the medical profession which is presumed to speak with authority on the matter of childen's diseases. I have appended the case histories briefly of a few of my personal experiences. They could be almost innumerably multiplied. Some appear commonplace and trite, but they teach a powerful lesson of the importance of breast-milk conservation. Each case lost to the breast adds its mite in influencing the sum total of the tremendous infant morbidity and infant mortality.

Case 3.—Mrs. J., mother of four children, and healthy, refused to nurse because she said that her milk poisoned her last baby, causing its death. The present infant was immediately placed on artificial nourishment and finally passed through its first year after experiencing two severe attacks of spasms and one attack of severe digestive disturbance. This could have been avoided by breast-feeding.

Case 4.—Mrs. M. had two children, both artificially fed. Both developed summer complaint and marasmus during the course of feeding, but finally recovered. The husband was a physician. The mother was told without reason that her milk was all water. She became pregnant again. From the day of conception, she was encouraged with reference to her ability to nurse her babe. After delivery intensity of moral support increased and she was well fed. Result: abundant milk-supply for ten months, and a healthy infant.
